# Ionic Liquids

## Ionic Liquids

Ionic liquids have gained importance as potential rocket propellants only during the past twenty years. This is a relatively recent development and ionic liquids are still being actively investigated while this book goes to print.

### 1 Definition of Ionic Liquids

The definition of ionic liquids (ILs) remains somewhat controversial; the scientific community tends to agree that salts that melt below 373 K (100 °C) are considered “ionic liquids.” This is an arbitrary limit and not scientifically founded. A narrower definition is “room-temperature ionic liquids” (RTILs) for those which remain in the liquid state at or below 298 K (25 °C). In order to achieve low melting points, ILs make use of bulky, asymmetric, poorly packing ions to lower their lattice energy. Favorite choices are quaternary ammonium and *N*-heteroaromatic cations. The *N*-heteroaromatic ions have been found to be very energetic when combined with appropriate counter ions. This arises from the numerous energetic N–N and C–N bonds and ring strains which lead to high enthalpies of formation. This property makes them suitable rocket propellants.

A commonly used acronym and abbreviation used for the term **Ionic Liquid** is **IL**. We have opted to use it in this chapter, and **ILs** in the case of the plural, as a means of saving space. Another acronym found in the literature is **RTIL** for **Room Temperature Ionic Liquid**. For use as rocket propellants, we are looking for **Energetic Ionic Liquids**, often abbreviated as **EILs**. In the literature, the term “**IL**” may include inorganic, low-melting salts such as hydroxylammonium nitrate (**HAN**).

One subset of ILs is the family of protic ILs (**pILs**), which are formed via proton transfer from a Brønsted acid to a Brønsted base [1]. As a result, **pILs** possess a proton-donor and a proton-acceptor site, which can build up a hydrogen bond (H-bond) network. However, depending on the compounds present and their **pKs**, the proton transfer may be less than complete, and, as a result, a mixture of two neutral liquids may be encountered. Doubly ionic H-bonds occur when an H-bond forms between a cation and anion, and these are a key feature of ILs [2]. H-bonds depress the melting point and alter the viscosity of imidazolium-based ILs, one of the main groups of ILs.

## 1.1 Introduction

This chapter deals only with organic ILs, and only with their preparation, and physical, thermal-stability, and safety properties. Applications of ILs as monopropellants will be discussed in *Encyclopedia of Monopropellants*. Applications of ILs as fuels in combination with hypergolic oxidizers will be discussed in *Encyclopedia of Hypergolic Bipropellant Combinations*. It is also possible that several ILs that should be listed here have already been described in *Encyclopedia of Liquid Fuels*, chapter “Heterocyclic and Heterocycloaliphatic Amines.” Some of these compounds are referenced repeatedly in this book because they have several applications.

Of all the chapters in this book, this IL chapter was the most difficult one to compile and to bring it up-to-date. This is because the technology is still actively under development and in flux. This chapter is an attempt to collect relevant literature, but it may not be complete. It is hoped that by the time a chapter on ILs as hypergolic fuels is added to a future set *Encyclopedia of Hypergolic Bipropellants* in several years from now, the surge of publications will have settled down and the real potential of these new fuels will become apparent.

The interest in ILs and their applications has led to the development of an extensive and diverse range of organic salts that can support low-melting-point IL phases (with examples ranging from simple mononuclear to complex anions) and the exploration of materials and applications utilizing the novel characteristics of these IL phases, including rocket propellants, explosives, heat-transfer fluids, lubricants, photovoltaics, and battery, capacitor, and fuel-cell electrolytes. In trying to organize the large amount of information that has become available on energetic ILs (EILs) during the past decades, several sorting criteria can be used for the following sections. One way of separating and sorting the information would be according to the intended application: as a rocket propellant, as a fuel for rocket bipropellant combinations, as a monopropellant, or as an explosive. Another way would be according to the number of atoms in the heterocyclic ring that forms the cation of the IL (most have five atoms), and then again by the number of heteroatoms (mostly nitrogen with 1–4 atoms) in the ring. Most of them have three nitrogens in a 5-membered ring placing them in the chapter on imidazole.

ILs consist of cations and anions. Typically, we sort ionic compounds by the cation first and the anion last. The difficulty in writing this chapter of the book is that most publications on ILs deal with more than one compound at the same time, requiring multiple entries in several subsections or they are dealing with the chemical compounds out of sequence from the general sorting scheme. Another way of subdividing the chapters would be to characterize the materials according to their physical, chemical, and safety properties, or by experimental and theoretical methods.

In any case, the literature cited in this book appears in chronological order, with the oldest references first and the most recent ones at the end of each chapter. This section contains mostly general information on ILs that applies to more than

one compound. Publications dealing with synthesis, properties, and applications of a specific IL, most of them heterocyclic compounds, have been moved to the sections in this book where the parent compounds (e.g. imidazole and 5-aminotetrazole) are discussed in systematic order.

In order to develop IL-based energetic materials, one typically looks for nitrogen-rich cations (imidazoles, triazoles, tetrazoles, hydrazine derivatives, and quaternary ammonium salts) in combination with oxygen-rich anions (nitrates, dinitramides, and perchlorates). One also has the option of souping up the performance by changing a traditional IL cation, like an imidazolium anion, into a nitroimidazolium anion by adding nitro groups to the ring structure. Depending on the energy content and the speed of energy release, such materials can behave either as high explosives or as energy-rich fuels. For instance, borohydride anion-based ILs have been proposed as hypergolic fuels for bipropellant combinations. Low vapor pressure and enhanced thermal stability are expected to yield low impact sensitivity of IL-based high-energy materials. Such materials should also retain their performance effectiveness after long-term storage, thus making them suitable for usage with weapons requiring long-term storability.

An advantage of ILs over the propellants they are intended to replace is their low vapor pressure, which makes them safer to handle and has earned them the designation of “green” (i.e. environmentally friendly) propellants. Many ILs solidify (i.e. they transition to a solid-glass state) at temperatures below the freezing point of the hydrazine(s) fuel or hydrazine monopropellant they are intended to replace, reducing the electric power requirements for propellant tanks and line heaters in satellites in cold regions of outer space. A disadvantage of ILs is their higher viscosity than conventional fuels, resulting in poor atomization when sprayed into a combustion chamber or an electrospray colloid thruster, and requiring higher feed pressures to overcome the fluid resistance in the feed system and injectors. The viscosity of a fluid arises from the internal friction of the fluid by mutual attraction of oppositely charged ions, and it manifests itself externally as the resistance of the fluid to flow. IL viscosities at room temperature range from a low of around 10 cPs to values in excess of 500 cPs. IL monopropellants (discussed in more detail in *Encyclopedia of Monopropellants*) have a higher density than hydrazine and a higher volume-specific impulse, which is a desirable property. However, up to now, there are no known catalysts that can spontaneously initiate the decomposition of IL monopropellants at room temperature. The less toxic monopropellants based on ammonium dinitramide (ADN) or HAN, which have now advanced to the status of orbital flight demonstrations, all require external electric power to pre-heat the catalyst and have long pre-heat response times.

Physical properties needed for the evaluation of ILs as rocket propellants are the freezing point (glass-transition point and melting point) and enthalpy of formation. Density is good to have if one wants to compare propellant combinations on the basis of volume-specific impulses. But densities of ILs based on organic heterocyclic amines are all very similar and would be easy to extrapolate. There is a lack of published en-

thalpies of formation for ILs and additional work is required to allow calculation of the specific impulse ( $I_{sp}$ ) for many of the compounds proposed as rocket propellants.

Many ILs are derived from heterocyclic amines, which is one reason why additional information on specific ILs can be found in *Encyclopedia of Liquid Fuels*, chapter “Heterocyclic and Heterocycloaliphatic Amines.” Besides being evaluated as rocket propellants, general interest in ILs as green solvents has increased in recent decades, primarily aiming at replacements for conventional media (solvents and absorbents) in chemical processes. ILs are an exciting class of compounds with unique properties that make them attractive for many other industrial applications, in addition to their proposed use as rocket propellants and explosives. Among their valuable features, an immeasurably low vapor pressure and a liquid state at or near ambient room temperature conditions are of interest to the rocket propellant chemist and safety evaluator. More than half of the literature cited in this chapter does not directly relate to rocket propulsion, but it provides the background information needed to develop more EILs.

Organic preparative chemists usually put their pride into preparing organic compounds that crystallize nicely and have sharp melting points; the melting point is often used as a criterion for purity. Quite often, the chemist gets frustrated by a compound that does not want to crystallize at room temperature. While this is usually considered a nuisance, now, all of a sudden, the unwillingness of an organic compound to crystallize becomes a desirable virtue if the compound remains a liquid at room temperature and can be used as an IL rocket propellant. Many of the ILs tend to supercool easily, forming glasses at very low temperatures rather than exhibiting sharp crystallization or melting transitions.

Initially, much of the focus in EIL research was on heterocyclic cations, in combination with oxygenated anions like nitrate and perchlorate which frequently have stability and safety problems. Later efforts expanded to other anions that made the liquids suitable as fuels instead of monopropellants or explosives. Other ILs with anions like tetrafluoroborate, hexafluorophosphate, and trifluoromethanesulfonate are of no use as rocket propellants but may serve as intermediates in the synthesis of more EILs.

## 1.2 Summary Information on ILs

For the researcher who intends to examine ILs as a group, the following literature sources may be useful. Some of this literature does not deal specifically with rocket propellants but is more of common interest, including many non-rocket applications of ILs.

The number of publications on ILs has increased exponentially during recent years (Figure 1) [3, 4]. As of August 2013, a search on SciFinder using the key words “ionic liquids” generated a list of 49426 publications. As of February 2021, this number had increased to 118709. Only few of these dealt with rocket propellants or explosives,

**Figure 1:** Total number of publications on ILs. (Reprinted from [3], with permission of ©2014 Royal Society of Chemistry; permission conveyed through Copyright Clearance Center Inc.)

so we selected a few and referenced them here. Most of the literature references on ILs evaluated as rocket propellants in this book are less than ten years old.

In addition to publications in periodicals and presentations at conferences, there are now several books devoted to ILs which are a good starting point for studies on these types of non-volatile rocket propellants. A book that provides many fundamentals about ILs, including history and pioneers was published in 2002 [5]. It lists many applications of ILs, but nothing about their use as rocket propellants. Surprisingly, the entire 3.6-MB book was once available to download for free on the Internet, but this is now a dead link [6].

A chapter in a book on applications of ILs in science and technology [7] gives a very useful overview of ILs for space propulsion applications [8]. It is available for downloading as an open-source document. It contains sections dealing with the use of ILs as monopropellants (HAN- and ADN-based), hypergolic bipropellants, and working fluids in electrospray thrusters.

An excellent summary on ILs for propellant and explosive applications is now available in [9]. This publication with its 158 references is a good starting point for the type of chemistry discussed in this chapter. Chapter 6 “Room temperature ionic liquids” [10] in a book on ILs [11] contains 464 references.

A summary on properties of mixtures of ILs containing information on 39 types of physicochemical properties for 1388 mixtures, including binary, ternary, quaternary, and other mixtures, is based on data gathered from 800 sources [12]. See also [13–17].

The chapter “Design and synthesis of green hypergolic ionic liquid fuels” in the book *High-Energy-Density Fuels for Advanced Propulsion: Design and Synthesis* is a summary of information on ILs and their hypergolic ignition capabilities [18]. In 1998, publication of a new journal, *Green Chemistry*, started which has since published numerous papers on ILs [19].

The National Institute of Science and Technology (NIST), the former National Bureau of Standards, maintains a database, the *NIST Standard Reference Database 147; NIST Ionic Liquids Database – IL Thermo* [20]. IL Thermo is a Web-based ILs database available for free to the public. It aims to provide users worldwide with up-to-date information on publications of experimental investigation on ILs, including numerical values of chemical and physical properties, measurement methods, sample purity, uncertainty of property values as well as many other significant measurement details. The database can be searched by means of the ions constituting the ILs, the ILs themselves, their properties, and references. The inaugural version of the database included data for more than 200 ions and more than 300 ILs as well as their binary and ternary mixtures. It contains well-organized and archived information on current and historical investigations on ILs, detailed descriptions of key elements in the experimental investigations such as sample purification and measurement methods, and up-to-date information on major publications on ILs. As of December 2013, it contained information on 1059 ILs and 796 pure IL compounds. Searching for “dicyanamide” produced 149 results, searching for “imidazolium” produced 2806 results, searching for a specialized item like “1-butyl-3-methylimidazolium dicyanamide” produced 44 results, but searching for “nitrate” failed. The database can be searched according to several criteria:

- Chemical identifier information on ions
- Chemical identifier information on ILs
- Binary mixture systems containing ILs
- Ternary mixture systems containing ILs
- Thermodynamic properties
- Thermochemical properties
- Transport properties

In several instances, it is possible to mix two solid substances and end up with an IL [21].

## 2 ILs Derived from Amines or Amides as Cations

The majority of ILs are derived from amines as cations. In this group, again subdividing according to the source of the cation, the majority of ILs known are derived from cations of heterocyclic amines. The anions with which the cations are paired can be either inorganic or organic. Anions that bring with them available oxygen would be preferred for ILs intended as monopropellants.

## 2.1 ILs Derived from Aliphatic Amines

The first IL considered as a rocket propellant was ethylammonium nitrate (EAN), which has a low melting (glass-transition) point of  $282\text{ K} = 9^\circ\text{C}$ . The properties of EAN were already described in *Encyclopedia of Liquid Fuels*, chapter “Aliphatic Amines.”

Throughout this chapter on ILs, the literature cited refers to either experimental or theoretical computational work on ILs, and sometimes to both modes of investigation. In this chapter, the different modes of investigation have not been separated, but are assembled in random arrangements next to each other in chronological order. Many publications deal with more than one type of IL, so these papers are cited at more than one location.

Classical molecular-dynamics (MD) computational chemistry simulations have been performed on 30 ILs at 298, 333, and 393 K, including ILs containing quaternary tetra-alkylammonium cations and dicyanamide (DCA), tricyanomethanide (TCM), tetracyanoborate, and nitrate anions [22]. The predicted IL density, heat of vaporization, ion self-diffusion coefficient, conductivity, and viscosity were found to be in good agreement with available experimental data.

The crystal structure and dimensions of *N,N,N,N*-tetramethylammonium(1+) DCA ionic salt was predicted by MD simulations and was in good agreement with experimental data [23]. Ion-counterion spatial distributions were used to understand the local environment and pairing of both ions in crystalline and liquid phases.

Five pILs with *n*-propylammonium or 3-hydroxypropylammonium as cations, and formate, acetate, or trifluoroacetate as anions, were synthesized and thermophysical properties such as density, viscosity, and velocity of sound were measured at various temperatures ranging from 293 to 343 K at atmospheric pressure [24]. The title of this paper is misleading. It meant to describe hydroxy**alkyl**ammonium ILs and has nothing to do with hydroxylammonium ions. The temperature dependence of experimental density and viscosity were fitted with second-order polynomial and Vogel–Tamman–Fulcher (VFT) equations, respectively. Thermal-decomposition temperature and glass-transition temperature, along with crystallization and melting point, were investigated using thermogravimetric analysis (TGA) and differential scanning calorimetry (DSC). The glass-transition temperatures were in the range 249–245 K (–24 to –28 °C).

The IL 2-(dimethylamino)-*N,N,N*-trimethylethanammonium DCA is hypergolic with white-fuming nitric acid (WFNA) and exhibits potential as a green fuel for bipropellants. Four energetic salts (including two ILs) based on 2-(dimethylamino)-*N,N,N*-trimethylethanammonium and *N,N'*-dialkyl-*N,N,N',N'*-tetramethylethane-1,2-diammonium were prepared and characterized by nuclear magnetic resonance ( $^1\text{H}$ - and  $^{13}\text{C}$ -NMR), infrared (IR), and Raman spectroscopy, and elemental analysis [25]. Physicochemical properties such as melting and decomposition temperatures, density, viscosity, enthalpy of formation, detonation performance, and  $I_{\text{sp}}$  were measured or calculated. The salts were stable up to 473 K (200 °C). The resulting ILs had densities from 1.02 to 1.19 g/cm<sup>3</sup> and enthalpies of formation from +85.1 to +154.4 kJ/mol.

Salts of the charge-delocalized cations of the triaminocyclopropenium (tac) family bearing alkyl substituents have been prepared and shown to be air- and water-stable ILs [26]. One example shown in the following structure is tris(dipropenylamino)cyclopropenium dicyanamidate.

The experimental results showed that all of these ILs exhibited the expected hypergolic reactivity with WFNA. Among them, the hypergolic IL based on the cyanoimidazolyl borohydride anion showed excellent properties, including a high onset of decomposition temperature 467 K (194 °C), high density (0.95 g/cm<sup>3</sup>), moderate viscosity (44 MPa · s), a very short ignition delay time (6 ms), and a high  $I_{sp}$  (302 s). This demonstrated its potential use as an environmentally friendly hypergolic fuel.

### 2.1.1 ILs Derived from Methylamine

Methylammonium nitrate melts at 381 K (108 °C) and is widely used as an ingredient in emulsion explosives. Its melting point is just outside the range of what are considered ILs. *Encyclopedia of Liquid Fuels*, chapter “Aliphatic Amines” contains a complete summary of the properties of methylammonium nitrate.

*Ab initio* molecular-dynamics (AIMD) simulations of the pIL methylammonium nitrate served to explain the effect of hydrogen bonding (H-bonding) on melting points of this relatively simple molecule [27]. It was easier to do these calculations for a simple molecule like methylammonium nitrate than for other ILs. Previous AIMD investigations had focused upon imidazolium-based ILs.

### 2.1.2 ILs Derived from Ethylamine

Ethylammonium nitrate, also known as ethylamine nitrate, EAN, H<sub>3</sub>CCH<sub>2</sub>NH<sub>3</sub>NO<sub>3</sub>, CAS RN [22113-86-6], is the simplest IL and is easy to obtain. The properties of EAN were already described in *Encyclopedia of Liquid Fuels*, chapter “Aliphatic Amines.” Its low melting point has aroused the curiosity of many chemists, but its use as a rocket propellant was not immediately recognized until J. D. Clark in his landmark book, *Ignition!*, commented: “Molten salts are nothing new, but these were the only ones I ever

heard of that were liquid at 25 °C. I've never found a use for the ethylamine compound, but something with such interesting properties ought to be good for something!" [28]. EAN is the first RTIL, with a melting point of 282 K = 9 °C, and it was first reported in 1914 [29].

Surface tensiometry of binary mixtures of EAN, ethanolanmonium nitrate (EtAN), and water revealed a distinctive amphiphilic character for the ethylammonium cation, but not for the ethanolanmonium cation [30]. Results also showed that the surface film incorporates nitrate counter ions, and that electrostatic and H-bonding interactions, rather than alkyl-chain packing, determine the saturated adsorbed film structure and limiting molecule area.

The rheologic properties of five pure pILs, EAN, *n*-propylammonium nitrate (PAN), EtAN, ethylammonium formate (EAF), and dimethylethylammonium formate (DMEAF), were characterized and interpreted by considering the effects of both the H-bond network and the solvo-phobic nanostructure of the liquids [31]. The results demonstrated that these effects are not independent or simply additive. At 293 K (20 °C), EtAN had the highest zero-shear viscosity of 156.1 mPa s, followed by PAN (89.3 mPa s), EAN (35.9 mPa s), EAF (23.1 mPa s), and DMEAF (9.8 mPa s). The primary ammonium ILs behaved as Newtonian fluids at low shear rates, but shear-thinned at high shear rates. The rheology of binary mixtures of these ILs was analyzed and used to demonstrate fundamental differences in the way IL cations and anions interact.

Multiple crystal pathways and crystal polymorphs were observed in pILs, which are liquids at room temperature [32]. The pILs investigated were methylammonium nitrate, dimethylammonium nitrate, EAN, and PAN. Methylammonium nitrate and dimethylammonium nitrate solidified as plastic crystals at room temperature, but EAN and PAN were liquids at room temperature. In spite of its simple molecular structure, complicated phase behaviors such as multiple crystal pathways and crystal polymorphs were observed in liquid EAN at a low temperature. Liquid PAN exhibited low-temperature anomalies similar to those observed with liquid EAN. Rapid proton exchanges, which disturb the crystal nucleation of pILs at room temperature, cause multiple crystal pathways via non-equilibrium states.

Low-melting alkylammonium nitrate ILs are useful as fuels for monopropellants, in combination with ADN or HAN as oxidizers. The melting behavior and thermal-decomposition mechanisms in the condensed phase of ADN/alkylammoniumnitrate mixtures during heating was measured using DSC and TGA-differential thermal analysis (DTA)-mass spectrometry (MS) [33]. Results showed that the melting point of ADN was significantly lowered upon the addition of alkylammonium nitrates with low molecular volumes and low melting points. TGA-DTA-MS results showed that the onset temperature of the thermal decomposition of ADN/alkylammonium nitrate mixtures was similar to that of pure ADN. ADN produced highly acidic products during thermal decomposition in the condensed phase that promoted exothermic reactions, nitration, and nitrosation of amines.

### 2.1.3 ILs Derived from 2-Hydroxyethylamine

One of the first ILs produced was probably 2-hydroxyethylammonium nitrate; also known as aminoethanol nitrate; ethanol, 2-amino-, nitrate (1:1);  $\text{HOCH}_2\text{CH}_2\text{NH}_3\text{NO}_3$ , CAS RN [20748-72-5], melting point (m.p.)  $325\text{--}328\text{ K} = 52\text{--}55\text{ }^\circ\text{C}$ ,  $\rho = 1.390\text{ g/cm}^3$ , in the year 1888 [34]. There are now hundreds of publications on ILs with the 2-hydroxyethylammonium cation, but mostly only with carboxylic acids, with particularly formic acid providing the anion [35, 36]. These ILs may be used as fuels or solvents, but they are not hypergolic. There was only very little work done on 2-hydroxyethylammonium cation paired with oxidizing anions like nitrate, perchlorate, or dinitramide.

The effect of step-by-step replacement of ethyl groups in triethylammonium nitrate by hydroxyethyl groups on properties of the ILs was investigated [37]. There were 32 salts with a melting point below 373 K.

If the remaining two hydrogens on the amino group of 2-hydroxyethylammonium nitrate are also replaced by hydroxyethyl groups, one obtains trihydroxyethylammonium nitrate (TEAN), which has once found extensive use as a fuel in liquid gun propellants (see *Encyclopedia of Monopropellants*).

### 2.1.4 ILs Derived from Other Aliphatic Amines

Three salts based on propan-2-ylidene methanetriamium cations and the DCA anion, *N*-(propan-2-ylidene) methanetriamium DCA, *N,N'*-bi(propan-2-ylidene) methanetriamium DCA, and *N,N',N''*-tri(propan-2-ylidene) methanetriamium DCA, were synthesized and characterized by  $^1\text{H}$ - and  $^{13}\text{C}$ -NMR, IR, and Raman spectroscopy, elemental analysis, TGA-DTA, and X-ray diffraction (XRD) [38]. Impact sensitivities were  $>40\text{ J}$  by drop hammer tests, which places these salts in the insensitive class. The salts were hypergolic with WFNA.

## 2.2 ILs Derived from O-Alkylhydroxylamines

IL salts derived from *O*-alkylhydroxylamines were already described in *Encyclopedia of Oxidizers*, along with other hydroxylammonium salts. The cations discussed there were derived from *O,O'*-methylenedioxamine,  $\text{H}_2\text{N}-\text{OCH}_2-\text{O}-\text{NH}_2$ , and *O,O'*-ethylenedi(oxamine),  $\text{H}_2\text{N}-\text{O}-\text{CH}_2-\text{CH}_2-\text{O}-\text{NH}_2$ , organic bases which can form mono- or diprotonated salts. *O,O'*-ethylenedi(oxamine) bis-dinitramide,  $[\text{H}_3\text{NOCH}_2\text{CH}_2\text{ONH}_3][\text{N}(\text{NO}_2)_2]_2$ , melts below 273 K, qualifying it as a RTIL. Its decomposition temperature is  $T_{\text{dec}} = 388\text{--}393\text{ K} = 115\text{--}120\text{ }^\circ\text{C}$ . *N*-Alkylhydroxylamines form IL salts that were already described in *Encyclopedia of Oxidizers*, chapter "Hydroxylammonium Salts."

## 2.3 ILs Derived from Aliphatic Amides

Guanidinium salts like guanidinium nitrate are well crystallized with high melting points. It requires organic substituents on the amido groups and different anions to obtain guanidinium ILs. Functionalized guanidinium ILs containing alkenyl functionalities have been developed as a new class of versatile organic materials, and characterized by measuring melting points, glass-transition temperatures, miscibility, densities, and surface tensions [39]. The physical properties of guanidinium dicyanoamidate ILs are summarized in Table 1

**Table 1:** Physical properties of guanidinium dicyanoamidate compounds.

| Cation              | Melting point |     | Decomposition onset |     | Density           | References |
|---------------------|---------------|-----|---------------------|-----|-------------------|------------|
|                     | K             | °C  | K                   | °C  | g/cm <sup>3</sup> |            |
| Guanidinium         | 330           | 57  | 418                 | 145 | 1.38              | [40]       |
| Aminoguanidinium    | 228           | 55  | 393                 | 120 | 1.41              | [41]       |
| Diaminoguanidinium  | 334           | 61  | 385                 | 112 | 1.36              | [41]       |
| Triaminoguanidinium | 397           | 124 | 423                 | 150 | 1.42              | [42]       |

The triaminoguanidinium dicyanamidate (dicyanamide, DCA) is not an IL but a solid which melts at 397 K (124 °C) and its enthalpy of formation is  $+400 \pm 7$  kJ/mol ( $+95.5 \pm 1.8$  kcal/mol). Since three of the four salts listed in Table 1 had melting points considerably below 373 K (100 °C), hypergolic ignition of the liquids was tested in simple drop tests with WFNA or nitrogen tetroxide (NTO). Details about these tests will be discussed in a future *Encyclopedia of Hypergolic Bipropellant Combinations*. At low temperatures, guanidinium dicyanoamidate exists in two different polymorphic phases with orthorhombic or monoclinic structures. Due to the chemical composition of guanidinium DCA,  $C_3N_6H_6$ , which is formally identical with that of melamine  $C_3N_3(NH_2)_3$ , and its facile conversion into melamine at around 400 K, guanidinium DCA may be suited as a molecular precursor for synthesis of graphitic carbon nitride materials.

Guanidinium octahydrotriborate, containing 13.8 mass-% hydrogen, has been prepared by a simple metathetic reaction

and has been evaluated as a hydrogen storage fluid [43]. Guanidinium octahydrotriborate is an IL with a melting point below 263 K (−10 °C). It decomposes selectively, starting at 343 K (70 °C) and maxing at 383 K (110 °C) to dihydrogen, and would most likely be hypergolic with WFNA or high-test peroxide (HTP).

Four types of guanidinium DCA-based energetic salts were prepared and investigated as energetic additives to the hypergolic IL fuel 1-ethyl-3-methylimidazolium dicyanamide ([Emim][DCA]) [44]. Their densities, viscosities, heats of formation,  $I_{sp}$ , ignition delay times, melting points, charge distributions, and decomposition temperatures were measured and calculated. The results showed that these salts possessed a high nitrogen content (>66 mass-%N), high density, and high  $I_{sp}$ . Their addition can bring significant improvement to the density and  $I_{sp}$  of [Emim][DCA] and would hardly affect its ignition delay time.

## 2.4 ILs Derived from Heterocyclic Amines

The current section deals only with ILs that have a heterocyclic cation and/or anion. There is some overlap between chapters on ILs, i.e. in *Encyclopedia of Liquid Fuels* in the chapter “Heterocyclic Amines,” here in the chapter “Ionic Liquids,” and in a later set on hypergolic combinations using ILs as fuels. It is common practice to abbreviate the names of heterocyclic ions in ILs by four-letter acronyms. Table 2 is a summary of commonly used acronyms.

**Table 2:** Acronyms used for heterocyclic cations in ILs.

| Acronym         | Complete name                          |
|-----------------|----------------------------------------|
| [Bmim], [C4mim] | 1-butyl-3-methylimidazolium            |
| [Dmim]          | 1- <i>n</i> -decyl-3-methylimidazolium |
| [Emim], [C2mim] | 1-ethyl-3-methylimidazolium            |
| [Hmim]          | 1-methyl-imidazolium nitrate           |
| [Hmim], [C6mim] | 1- <i>n</i> -hexyl-3-methylimidazolium |
| [Mmim]          | 1,3-dimethylimidazolium                |

This first series of sections on ILs deals with preparation and properties of ILs not especially intended as hypergolic fuels or explosives. Later on in this chapter is a series of sections in a very similar sequence, concentrating on ILs intended as hypergolic fuels in bipropellant combinations. There may be some overlap between these two components of this chapter. Separating the ILs intended as hypergolic fuels into a subsection made the large amount of information more manageable.

### 2.4.1 Preparation of ILs Derived from Heterocyclic Amines

The preparation of ILs from the parent heterocyclic amines is usually pretty straightforward: an acid–base reaction of stoichiometric amounts of base and acid, conducted in a solvent as a diluent with adequate cooling to conduct away the heat of neutralization. After removal of the solvent, the salts may or (most often) may not

crystallize. They have a tendency to supercool and may require seed crystals to obtain a solid phase for XRD structure determination at low temperatures. Some do not have a freezing point but only a glass-transition point at low temperatures. In most cases, for rocket applications, the heterocyclic amine forms the cation and it is paired with the anion of a strongly oxidizing inorganic acid, such as nitrate, perchlorate, or dinitramide. Salts that are formed with hexafluorophosphate or tetrafluoroborate anions are of less interest to rocket propulsion. They might be used as intermediates in the synthesis of more energetic compounds or as electrolytes in batteries or capacitors. Other ILs exist where both the cation and the anion are heterocycles.

While first-generation ILs often had at least one inorganic ion, other ILs have now been synthesized that contain azonium cations and azolate anions [45]. Triazole and tetrazole were coupled with 1-ethyl-3-methylimidazolium hydroxide, and the obtained tetrazolium salt was a liquid at room temperature showing a glass-transition temperature at 184 K (−89 °C.)

#### 2.4.2 ILs Derived from Azetidine

The parent molecule of azetidinium-derived ILs is azacyclobutane, also known as azetidine, azetane, CAS RN [503-29-7], which was already described in *Encyclopedia of Liquid Fuels*, chapter “Heterocyclic Amines.”

A group of azetidinium-based hypergolic ILs was synthesized and characterized by  $^1\text{H}$ - and  $^{13}\text{C}$ -NMR and IR spectroscopy, and electrospray ionization mass spectrometry (EIMS) [46]. The ILs were made by quaternizing 1-*n*-butylazetidine with methyl, ethyl, propyl, allyl, propynyl, or butyl iodide or bromide, and replacing the halogenide anion by a reaction with silver DCA. The properties of six synthesized ILs were characterized with respect to liquid range, density, viscosity, enthalpy of formation, and ignition delay time with WFNA. In order to better understand the relation between ring strains and the energy of obtained compounds, the isomers of 1-*n*-butyl-1-propyl-azetidinium dicyanamidate (BPAD) were also synthesized for comparison. It was found that compared with the isomers, BPAD exhibited a much higher enthalpy of formation (difference of +0.78 kJ/g), which indicated that ring strains play an important role in the performance of these energetic compounds. BPAD had the highest enthalpy of formation, +2.17 kJ/g.

#### 2.4.3 ILs Derived from Pyrrolidine

Pyrrolidine is the fully hydrogenated pyrrole.

Pyrrole

Pyrrolidine

Pyrrolidinium nitrate,  $C_4H_{10}N_2O_3$ , CAS RN [129228-91-7],  $M = 134.13$  is a low-melting IL. Property data for this well-characterized salt have already been summarized in *Encyclopedia of Liquid Fuels*, chapter “Aliphatic Amines.” A batch of pyrrolidinium nitrate exploded while drying it under reduced pressure at 383 K (110 °C), using a rotary evaporator with a silicone oil bath [47]. Therefore, precautions are necessary when working with any amine nitrate or perchlorate.

A family of low-cost and easily prepared azide-functionalized cation-based ILs, including fuel-rich anions, such as nitrate, DCA, and nitrocyanamide anions, were synthesized and characterized [48]. All the DCA- and nitrocyanamide-based ILs exhibited spontaneous combustion upon contact with 100%  $HNO_3$ . The densities of these hypergolic ILs varied within the range 1.11–1.29 g/cm<sup>3</sup>, and the density-specific impulse, predicted based on Gaussian 09 calculations, was between 289.9 and 344.9 s g cm<sup>-3</sup>. The values of these two key physical properties were much higher than those of unsymmetrical dimethylhydrazine (UDMH). 1-(2-Azidoethyl)-1-methylpyrrolidin-1-ium DCA showed excellent properties including the lowest viscosity (30.9 MPa s), a wide liquid operating range (203–478 K = –70 to 205 °C), the shortest ignition delay time (7 ms) with 100%  $HNO_3$ , and a superior density-specific impulse (302.5 s g cm<sup>-3</sup>).

#### 2.4.4 ILs Derived from Imidazole

Imidazole itself is not useful as a rocket propellant. The interest in imidazole(s) as a rocket propellant ingredient stems mostly from the low melting point of the imidazolium salts, which puts them into the category of “ionic liquids.” The most commonly shown structural formula is 1*H*-1,3-imidazole

Imidazole

although compounds derived from other imidazoles (2*H*-imidazole and 4*H*-imidazole) are known.

In searching for the ideal IL, the effect of substitution on the heterocyclic ring on physical properties of the resulting salts has been thoroughly investigated. Imidazole-based ILs are of particular interest because they can serve as monopropellants and as working fluids in electrospray colloid thrusters. The IL, 1-ethyl-3-methylimidazolium bis(trifluoromethylsulfonyl)imide ([Emim][Im]) has already been used in colloid, or electrospray, thruster applications. Due to their favorable electrochemical properties, several other imidazole-based ILs are under consideration for electrospray propulsion.

#### 2.4.4.1 Preparation of ILs Derived from Imidazole

1-Butyl-3-methylimidazolium 3,5-dinitro-1,2,4-triazolate [Bmim], [C4mim], exhibited an unexpectedly low melting point ( $308\text{ K} = 35^\circ\text{C}$ ) [49, 50]. ILs (defined as having a  $\text{m.p.} < 373\text{ K} = < 100^\circ\text{C}$ ) were obtained with all combinations of the Bmim cation and the heterocyclic azolate anions studied, and with several combinations of tetraethyl or tetrabutylammonium cations and the azolate anions. The  $[\text{C4mim}]^+$  azolates were liquids at room temperature, exhibiting wide liquid ranges and forming glasses upon cooling with glass-transition temperatures in the range of  $220\text{--}191\text{ K}$  ( $-53$  to  $-82^\circ\text{C}$ ).

Analogous tetra-alkylammonium (methyl, ethyl, and *n*-butyl) triazolate salts have also been prepared, but they all melted above  $373\text{ K}$ , and the tetraethylammonium example was characterized by single-crystal XRD.

ILs can be custom-designed to meet certain desired properties by attaching active substituents to an imidazole platform and pairing it with the correct anion [51]. It is not yet possible to accurately predict the thermodynamic properties of ILs just from their chemical structure alone, although attempts in this direction have been made [52].

The molar enthalpy of formation of the IL [Bmim][DCA] was measured by means of combustion calorimetry to be  $+206.2 \pm 2.5\text{ kJ/mol}$  and the molar enthalpy of vaporization was obtained from the temperature dependence of the vapor pressure measured using the transpiration method and found to be  $157.2 \pm 1.1\text{ kJ/mol}$  [53]. The enthalpy of formation of gaseous [Bmim][DCA] is  $+363.4 \pm 2.7\text{ kJ/mol}$ .

Densities and viscosities of 1-butyl-3-methylimidazolium nitrate [Bmim][NO<sub>3</sub>] and its binaries with alcohols (ethanol, 1-propanol, or 1-butanol) were measured at different temperatures [54]. The densities and viscosities of pure ILs were correlated successfully by empirical equations.

Classical MD computational chemistry simulations have been performed on 30 ILs at  $298$ ,  $333$ , and  $393\text{ K}$ , including ILs containing 1-methyl-3-alkylimidazolium,

1-alkyl-2-methyl-3-alkylimidazolium cations with different-length alkyl chains, and DCA, TCM, tetracyanoborate, and nitrate anions [22]. The IL density, heat of vaporization, ion self-diffusion coefficient, conductivity, and viscosity were found to be in good agreement with available experimental data.

Thirty-one salts were synthesized by pairing diverse cations (Bmim, and tetramethyl-, tetraethyl-, and tetrabutylammonium) with azolate anions (5-nitrobenzimidazolate, 5-nitrobenzotriazolate, 3,5-dinitro-1,2,4-triazolate, 2,4-dinitroimidazolate, 4-nitro-1,2,3-triazolate, 4,5-dinitroimidazolate, 4,5-dicyanoimidazolate, 4-nitroimidazolate, and tetrazolate) [55]. These salts were characterized by DSC, TGA, and single-crystal XRD. The azolates in general were surprisingly stable in the systems explored. ILs were obtained with all combinations of the Bmim cation and the heterocyclic azolate anions studied, and with several combinations of tetraethyl- or tetrabutylammonium cations and the azolate anions. Favorable quantitative structure–property relationships (QSPRs) were most often achieved when changing from 4- and 4,5-disubstituted anions to 3,5- and 2,4-disubstituted anions. The most promising anion for use in energetic ILs of those studied here, was 3,5-dinitro-1,2,4-triazolate, based on its contributions to the entire set of desired properties.

1-(2-Hydroxyethyl)-3-methylimidazolium dicyanamidate [C2OHmim][DCA],  $C_8H_{11}ON_5$ , has a density of  $1.12\text{ g/cm}^3$  and a heat capacity of  $1.20\text{ J g}^{-1}\text{ K}^{-1}$ . The standard molar enthalpy of formation of the IL [C2OHmim][DCA] has been determined by means of combustion calorimetry. The heat of combustion of liquid [C2OHmim][DCA] was  $4793.0 \pm 2.1\text{ kJ/mol}$  and the enthalpy of formation was  $+72.9 \pm 2.3\text{ kJ/mol}$  [56]. First-principles calculations of the enthalpy of formation in the gaseous phase have been performed for the ionic species. The combination of combustion calorimetry with the high-level quantum chemical calculations allowed an estimation of the molar enthalpy of vaporization of the IL. The liquid-phase enthalpy of formation of this IL can be estimated by extrapolating from group additivity rules.

Vaporization enthalpies of 1-ethyl-3-methylimidazolium tricyanomethanide [C2mim][C(CN)<sub>3</sub>],  $C_{10}H_{11}N_5$ , CAS RN [666823-18-3], and 1-butyl-3-methylimidazolium tricyanomethanide [C4mim][C(CN)<sub>3</sub>],  $C_{12}H_{15}N_5$ , CAS RN [878027-73-7] were measured in the range 400–453 K by a quartz microbalance method [57]. The enthalpies of formation of the two liquid ILs derived from the heat of combustion in a calorimeter were  $+342.2 \pm 2.5$  and  $+279.2 \pm 2.6\text{ kJ/mol}$ , respectively.

For comparison, the enthalpies of formation of the corresponding DCA salts in the liquid state are [C2mim][N(CN)<sub>2</sub>]  $+235.3 \pm 3.1\text{ kJ/mol}$  and [C4mim][N(CN)<sub>2</sub>]  $+195.0 \pm 2.7\text{ kJ/mol}$  [53, 58]. For comparison, the enthalpies of formation of the corresponding nitrate salts in the liquid state are [C2mim][NO<sub>3</sub>]  $-216.9 \pm 2.0\text{ kJ/mol}$  and [C4mim][NO<sub>3</sub>]  $-261.4 \pm 2.9\text{ kJ/mol}$  [59].

Commercially available 1-butyl-3-methylimidazolium nitrate and 1-ethyl-3-methylimidazolium sulfate were used as fuels for monopropellant blends with HAN as the oxidizer [60–63]. Such mixtures can potentially also be used in electrospay thrusters in dual-mode satellite propulsion systems.

The possibility of forming simple EILs via the straightforward protonation of heterocyclic amines with nitric or picric acid was explored with 1-alkylimidazoles, 1-alkyl-2-methylimidazoles, and nitro-, dinitro-, and dicyano-substituted derivatives of imidazole [64]. The melting points of most of the prepared salts were lower than expected, and of the 30 compounds prepared, more than half were found to melt below 373 K (100 °C). For example, 1-methyl-3*H*-imidazolium nitrate melted at 333 K (60 °C) and its decomposition started at 410 K (137 °C). It was found that energetic electron-withdrawing substituents, such as nitro or cyano, will result in a reduction in nucleophilicity of the heterocycle and an inability to form salts with the acids studied. Unusual thermal behavior was observed with several of the new salts including supercooling and crystallization on heating. Comparison of the singly protonated imidazolium nitrate and picrate salts with their methylated analogs indicated that the protonated ILs did not differ substantially in their melting points from the methylated analogs. However, the thermal stabilities of protonated imidazolium salts were much lower than their alkylated derivatives. Nitrate salts with alkylated cations tended to be more thermally stable than the corresponding picrate salts; however, with protonated cations, the picrate salts tended to be approximately 70–80 °C more stable than the nitrate salts. Accelerating-rate calorimetry (ARC) revealed that alkylated salts decomposed much less exothermically (in some cases endothermically) than the protonated analogs. Among all the analyzed salts, the most energetic materials were 1-methylimidazolium nitrate and 1,2-dimethylimidazolium picrate.

*N,N*-Bis(1*H*-tetrazol-5-yl)amine anions (HBTA<sup>−</sup> and BTA<sup>2−</sup>) were used as nitrogen-rich components for the construction of EILs. Seven ILs, namely, **(1)** 1,3-dimethylimidazolium [C1mim]HBTA, 1-ethyl-3-methylimidazolium **(2)** [C2mim]HBTA, 1-butyl-3-methylimidazolium **(3)** [C4mim]HBTA, 1-hexyl-3-methylimidazolium **(4)** [C6mim]HBTA, 1-methyl-3-octylimidazolium **(5)** [C8mim]HBTA, and 1,2,3-trimethylimidazolium **(6)** [C1Mmim]HBTA cations with the HBTA<sup>−</sup> anion and di-1,2,3-trimethylimidazolium *N,N*-bis(1*H*-tetrazol-5-yl)amine and **(7)** [C1Mmim]<sub>2</sub>BTA were synthesized and characterized by IR and NMR spectroscopy, elemental analysis, and high-resolution MS (HR-MS) [65]. The crystal structures of **(1)** and **(7)** were determined by single-crystal XRD **(1)**: monoclinic, space group *P*2<sub>1</sub>/*n*,  $\rho = 1.511 \text{ g/cm}^3$ ; **(7)** monoclinic, space group *P*2<sub>1</sub>/*c*,  $\rho = 1.221 \text{ g/cm}^3$ . The ILs **1–7** were thermally stable to 493 K (220 °C), and **2–5** were RTILs. The heats of formation of **1–7** obtained by both experimental and theoretical methods were all positive. The ILs **1–7** were insensitive to impact (>40 J) and friction (>360 N). They could be ignited in air. These new EILs contain only C, H, and N, and are of interest as potential propellants with high energy, high thermal stability, low sensitivity to impact and friction, and environmentally friendly decomposition products.

The energy contents of [Emim]<sup>+</sup>-based EILs have been studied via the formation of their ion pair [Emim]<sup>+</sup>[X]<sup>−</sup>, using G3MP2 and density functional theory (DFT) methods [66, 67]. The selected anions included nitrogen-rich derivatives of tetrazolate and triazolate, dinitramidate, and dicyanamidate as well as the conventional anions BF<sub>4</sub><sup>−</sup> and PF<sub>6</sub><sup>−</sup>. The nitrogen enrichment in the system produces EILs which showed compa-

rable and, in some cases, superior thermochemical, fluid, and  $I_{sp}$  properties to conventional ILs. The binding energy values for  $[\text{Emim}]^+[\text{X}]^-$  were in the range of 336–400 kJ/mol at DFT levels, while the atomization procedure used to compute their enthalpy of formation ( $\Delta H_f$ ) at the G3MP2 level produced results in very close agreement with available experimental data (maximum deviation <5%). The  $\Delta H_f$  of conventional ILs is negative whereas that of EILs (167–559 kJ/mol) confirmed their high-energy state. The predicted  $I_{sp}$  of all EILs was slightly lower than hydrazine in monopropellant systems, but a significant increase in  $I_{sp}$  was observed with the addition of HAN. A linear correlation between  $I_{sp}$  and the sum of nitrogen and oxygen mass-% of the EILs was observed. Measured enthalpies of formation for  $[\text{Emim}][\text{DCA}]$  and  $[\text{Bmim}][\text{DCA}]$  are +391.7 and +363.4 kJ/mol, respectively.

The combustion of 1-ethyl-3-methyl imidazolium cyanoborohydride ( $[\text{Emim}][\text{BH}_3\text{CN}]$ ) and 1-allyl-3-ethyl imidazolium cyanoborohydride ( $[\text{AEIM}][\text{BH}_3\text{CN}]$ ), and catalyzed additive mixtures with 95%  $\text{H}_2\text{O}_2$  has been investigated [68]. 1,3-Dimethylimidazolium iodocuprate ( $[\text{dimim}]_n[\text{Cu}_2\text{I}_3]_n$ ) was synthesized and dissolved in ILs. A 2–15 mass-% of  $[\text{dimim}]_n[\text{Cu}_2\text{I}_3]_n$  in  $[\text{Emim}][\text{BH}_3\text{CN}]$  and 15 mass-% of  $[\text{dimim}]_n[\text{Cu}_2\text{I}_3]_n$  exhibited ignition delay time values of 13 and 29 ms under fuel-rich and oxidizer-rich conditions, respectively. These ignition delay time values were 100 times lower than those for the  $[\text{Emim}][\text{BH}_3\text{CN}]$  solvent by itself.  $[\text{dimim}]_n[\text{Cu}_2\text{I}_3]_n$ - $[\text{Emim}][\text{BH}_3\text{CN}]$  solutions have high density ( $>0.98 \text{ g/cm}^3$ ), good thermal stability ( $T_{\text{dec}} > 473 \text{ K} = > 200^\circ\text{C}$ ), and a density-specific impulse 5.6–6.0% higher than that of UDMH.

Two ILs,  $[\text{Emim}][\text{BH}_3\text{CN}]$  and its zwitterion 1-methyl imidazolium borane ( $\text{mimBH}_3$ ), were evaluated as bipropellants with 95%  $\text{H}_2\text{O}_2$  as the oxidizer [69]. A 9 mass-% solution of sodium iodide in  $[\text{Emim}][\text{BH}_3\text{CN}]$  and in a blend of  $[\text{Emim}][\text{BH}_3\text{CN}]$ :furfuryl alcohol (1:1 by mass) had an ignition delay time of ~75 and 56 ms, respectively. These ignition delay times were a hundred times lower than those of the neat fuel  $[\text{Emim}][\text{BH}_3\text{CN}]$ .

It is generally assumed that there is a relationship between the ignition delay time and the viscosity of hypergolic energetic ILs. With this presumption, an investigation was made to obtain the best logical relationships between the ignition delay time, viscosity, and molecular structure of hypergolic imidazolium ILs [70]. The 3D chemical structures of a collected database of 50 imidazolium ILs were encoded into a total number of 3250 diverse types of molecular descriptors, which are representatives of various physicochemical properties of these ILs. A multiple linear regression/artificial neural network (MLR-ANN) statistical approach was applied to obtain the most important molecular descriptors on these relationships. The obtained results for the proposed 3D QSPR models were applied as a criterion for designing new hypergolic imidazolium ILs with the desired short ignition delay time and low viscosity. The predictive ability of the final models derived was evaluated by both internal and external validation methods. This computational method can enable computer-aided molecular design researchers to identify or design new high-energy ILs with optimum physicochemical properties.

#### 2.4.4.2 Thermal Stability of ILs Derived from Imidazole

The thermal stability of ILs is usually determined with the DTA, TGA, DSC, or ARC methods, or by gas evolution volumetric measurements. Because of the unusually high heats of vaporization of RTILs, volatilization of RTILs through thermal decomposition and vaporization of the decomposition products can be significant. Heats of vaporization were determined by a similar method. Upon further heating of cyano-functionalized anionic RTILs in vacuum, their gaseous products were detected experimentally via tunable vacuum ultraviolet (VUV) photonionization (PI) MS [71–73]. Experimental evidence for di- and trialkylimidazolium cations and cyano-functionalized anionic RTILs confirmed that the thermal decomposition occurred primarily via two pathways: deprotonation of the cation by the anion and dealkylation of the imidazolium cation by the anion. Secondary reactions included possible cyclization of the cation and C2 substitution on the imidazolium. Additional evidence supporting these mechanisms was obtained using TGA-MS, gas chromatography MS (GC-MS), and temperature-jump IR spectroscopy. The ability to predict the overall thermal stability in these ILs depends on knowledge of both the basicity of the anions and their nucleophilicity. DFT calculations were conducted to model the decomposition mechanisms, and these could provide a method to predict thermal stabilities for ILs in general.

The thermal stability and thermokinetic parameters of 1,3-dimethylimidazolium nitrate, [Mmim]NO<sub>3</sub>, were examined by TGA under non-isothermal conditions in a nitrogen atmosphere [74]. The results showed that [Mmim]NO<sub>3</sub> exhibited three decomposition stages from 366 to 623 K (93.3–350 °C), and the onset temperature of [Mmim]NO<sub>3</sub> was 161–182 °C, depending on the heating rate. The apparent activation energy was 119.0–124.0 kJ/mol and the pre-exponential factor was  $3.6 \times 10^{12} \text{ min}^{-1}$ . Vent-sizing package 2 was employed to acquire the maximum self-heating rate (39828 °C/min) and pressure rise rate (73331 psi/min) for simulating cooling system failure in a closed-vessel practical process. The findings indicated that [Mmim]NO<sub>3</sub> has the possible hazard of a runaway reaction.

In an investigation of the short- and long-term stability of several 1-alkyl-3-methylimidazolium halides, determination of the degradation products, and the elucidation of their decomposition patterns and structure–stability relations, the short-term stability and mechanism of thermal degradation were investigated with a thermal-analysis, single-photon ionization time-of-flight (TOF) MS device [75]. This instrument allowed real-time monitoring of the forming species and allowed tracing of their change during the course of the decomposition. The almost fragment-free soft ionization with VUV photons plays a crucial role. Unfragmented molecules were detected whose formation was only assumed by electron ionization. The main decomposition products of the selected ILs were alkyl imidazoles, alkenes, alkyl halides, and hydrogen halides. Long-term thermal stability was determined based on TGA evaluated with a kinetic model. The time-dependent maximum operation temperatures for these ILs have been calculated.

The thermal stability of [Mmim]NO<sub>3</sub> was investigated by simultaneous TGA and high-pressure DSC [76]. Isothermal experiments indicated that [Mmim]NO<sub>3</sub> might already decompose at a temperature substantially lower than the DSC onset temperature. A pseudo-zero-order-rate expression was applied to characterize the thermal decomposition kinetics of [Mmim]NO<sub>3</sub>. The temperature at which the thermal decomposition of ILs reached 10.0% for a given time of 10 h (T 0.1/10 h) was defined to assess the long-term thermal stability, which should be used as the maximum safe operating temperature of [Mmim]NO<sub>3</sub>.

## 2.5 ILs Derived from Triazole

As already described in detail in *Encyclopedia of Liquid Fuels*, chapter “Heterocyclic Amines,” there are two triazole isomers, 1,2,3-triazole and 1,2,4-triazole.

Both serve as the parent molecule for a multitude of ILs, modified by substituting one, two, or three hydrogens on the ring with melting point-lowering and energy-increasing groups. Most of these are used in the form of triazolium cations.

Drake and co-workers [77, 78] prepared EILs by combining cations containing energetic functionality with relatively small inorganic energetic anions ([NO<sub>3</sub>]<sup>−</sup>, [ClO<sub>4</sub>]<sup>−</sup>, and [N(NO<sub>2</sub>)<sub>2</sub>]<sup>−</sup>). In this work, and related work by Xue, Shreeve, and coworkers [79, 80], energetic low-melting organic salts contained amine-functionalized triazoles and tetrazoles as cations. It was suggested that the ready formation of ILs with these cations appeared to be due to a similarity of topographical shape and charge distribution with conventional IL systems.

### 2.5.1 Triazolium-Based Energetic Ionic Salts

A comparison of the thermal stability of heterocyclic amines has led to the discovery that the incorporation of amino groups into a heterocyclic triazole ring is one of the simplest routes to enhance thermal stability. The *N*-amino group behaves as an electron-withdrawing group in these high-nitrogen heterocycles that, when paired with nitrate, perchlorate, or dinitramide anions, form energetic salts potentially useful as rocket propellants. 4-Amino-1,2,4-triazolium or 1-amino-1,2,4-triazolium

salts are formed by the reaction of 4-amino-1,2,4-triazole or 1-amino-1,2,4-triazole with  $\text{HNO}_3$ ,  $\text{HClO}_4$ , or  $\text{HN}(\text{NO}_2)_2$ , respectively. In addition to the amino substituent on the triazole ring, substitution of additional ring-bound hydrogens with methyl, trifluoromethyl, alkyl, perfluoroalkyl, azido, or azidoethyl groups leads to a wide variety of EILs. Ionic salts containing longer alkyl and polyfluoroalkyl substituents have lower melting points because of less-efficient packing in the solid.

4-Amino-1,2,4-triazole was the readily available starting material for the synthesis of 1-R-4-amino-1,2,4-triazolium bromide salts, which, by subsequent metathesis with the appropriate silver salts, led to several new nitrate, perchlorate, and nitro-cyanamide ILs [81]. Compounds with alkyl side chains including R = methyl, ethyl, *n*-propyl, isopropyl, *n*-butyl, methylcyclopropyl, 2-propenyl(allyl), and 2-hydroxyethyl were synthesized via this reaction pathway. These ILs were characterized by vibrational spectroscopy, multi-nuclear NMR, elemental analyses, DSC, and impact and friction sensitivity tests. Most of the salts were liquid at ambient temperatures, with melting points well below room temperature. All materials were stable at room temperature and showed no signs of decomposition even after over one year of storage at ambient temperatures.

1,2,4-Triazolium ILs are a practical alternative to imidazolium ILs [82]. Direct quaternization of 1-methyl-1,2,4-triazole with *n*-alkyl methanesulfonates (alkyl = butyl, octyl, and dodecyl) with subsequent metathesis with lithium bis-(trifluoromethanesulfonyl)amide is a convenient, solvent- and halide-free way to obtain 1,2,4-triazolium methanesulfonate ILs in high purity and yield. DSC confirmed that all investigated compounds qualify as ILs. 1-Methyl-4-*n*-dodecyl-1,2,4-triazolium methanesulfonate showed a rather complex thermal behavior involving formation of mesophases. Polarizing optical microscopy showed oily, streaky textures that are characteristic for smectic liquid crystalline phases. Single-crystal XRD structure analysis confirmed formation of a layered structure. All compounds were photoluminescent. All ILs showed an appreciable liquidus range and thermal (up to 260–350 °C) and electrochemical stability.

The  $\Delta H_f$  of some EILs was predicted from the quantum mechanical energies of molecules using an atomization approach [83]. The enthalpies of formation for substituted gas-phase triazolium cations were calculated by G2 and DFT Becke, 3-parameter, Lee–Yang–Parr (B3LYP) methods. The  $\text{N}_3$  and CN substituents at the 1,2,4-triazolium ring's nitrogen atoms led to the highest values of  $\Delta H_f$ .

Hypergolic fuels based on 1-ethyl-4-methyl-1,2,4-triazolium iodide,  $[\text{EMT}]^+[\text{I}]^-$  were synthesized by nucleophilic substitution and characterized by IR and  $^1\text{H}$ -NMR spectroscopy and GC-MS [84]. The hypergolic chemicals  $[\text{EMT}]^+[\text{X}]^-$  ( $\text{X} = \text{CN}^-$ ,  $\text{N}_3^-$ ,  $\text{NO}_3^-$ ,  $\text{NO}_2^-$ ,  $\text{ClO}_4^-$ ,  $\text{AlCl}_4^-$ ) were prepared via ion exchange reactions from  $[\text{EMT}]^+[\text{I}]^-$ . The salts were dissolved in 2-hydroxyethylhydrazine (2-HEH), and the decomposition temperature, density, viscosity, and decomposition energy were evaluated to determine their suitability for use as liquid rocket fuels. The ignition delay time of the mixture of hypergolic chemicals with  $[\text{EMT}]^+[\text{N}_3]^-$ ,  $[\text{EMT}]^+[\text{CN}]^-$ ,

$[\text{EMT}]^+[\text{AlCl}_4]^-$ , and  $[\text{EMT}]^+[\text{I}]^-$  using HTP as an oxidizer was 18, 33, 28, and 8 ms, respectively.

*Encyclopedia of Liquid Fuels*, chapter “Heterocyclic Amines” contains a summary of the predicted enthalpies of formation of triazolium salts. Several of these have very low melting points.

## 2.6 ILs Derived from Tetrazole

The high nitrogen content of tetrazole and its derivatives has led to ongoing investigations into their use as potential energetic materials. Some of these derivatives have low melting or glass-transition points and are classified as ILs.

### 2.6.1 ILs Derived from Mono-Substituted Tetrazole

Eight 5-aminotetrazolate (5-AT) salts based on the 1,2,3-trimethylimidazolium (**1**), 1,3-dimethylimidazolium (**2**), 1-ethyl-3-methylimidazolium (**3**), 1-butyl-3-methylimidazolium (**4**), 1-isobutyl-3-methylimidazolium (**5**), 1-(3'-methylbutyl)-3-methylimidazolium (**6**), 1-hexyl-3-methylimidazolium (**7**), and 1-methyl-3-octylimidazolium (**8**) cations have been synthesized and characterized by IR and NMR spectroscopy and elemental analysis [85]. Based on DSC/TGA, these salts decomposed within the temperature range 296–535 K (230–262 °C). Salts **3–8** were very fluent RTILs, whose glass-transition temperatures were quite low. Their viscosities at 303 K (30 °C) were in the range of 92–208 cPs. The standard enthalpy of formation of salts **1–8** was predicted by theoretical methods. Salt (**2**) with the 1,3-dimethylimidazolium cation had the highest positive enthalpy of formation. These 5-AT salts were insensitive to impact (>40 J) and friction (>360 N). Hypergolic reactions of these 5-AT salts with 100%  $\text{HNO}_3$  were also examined but only a few ignited.

### 2.6.2 ILs Derived from Tri-Substituted Tetrazole

1,5-Diamino-4-methyltetrazolium dinitramide melts at <100 °C, which places it in the category of an EIL. One of the first oxygen-balanced ILs in this category was 1-ethyl-4,5-dimethyltetrazolium tetranitratoaluminate [86, 87]. In this IL molecule, the tetranitratoaluminate anion contains 12 oxygen atoms; of these, 10.5 are available to oxidize a fuel cation. The 1-ethyl-4,5-dimethyltetrazolium cation was chosen because of its positive enthalpy of formation and its ability to form an RTIL with the tetranitratoaluminate anion. The resulting energetic salt is a colorless liquid at room temperature. Its spontaneous ignition temperature was 473 K (200 °C). This is the end of the section on ILs based on 5-membered heterocyclic rings. The following sections will describe ILs based on 6-membered heterocyclic rings.

## 2.7 ILs Derived from Pyridines

Pyridinium salts containing cyanoborohydride or DCA anions are hypergolic with the oxidizer red-fuming nitric acid (RFNA). Imidazolium and triazolium compounds are ten times more expensive than pyridinium salts, so there is an economic incentive to thoroughly evaluate pyridinium ILs as hypergolic fuels. Hypergolic ILs containing  $[\text{BH}_3\text{CN}]^-$  have shorter ignition delays (4 ms) and are less expensive than the  $[\text{BH}_2(\text{CN})_2]^-$  anion and less sensitive to water than those with  $\text{BH}_4^-$  and  $[\text{Al}(\text{BH}_4)_4]^-$ . The pyridinium salts of interest are those derived from 4-aminopyridine and quaternized with butyl and allyl chloride [88]. The chloride ion is then replaced by metathetical reactions with silver and sodium salts of the cyan-containing anions. Ignition delays of these fuels with RFNA will be discussed in a future *Encyclopedia of Hypergolic Bipropellant Combinations*.

*N*-Methylpyridinium salts  $[\text{MPy}]^+[\text{X}]^-$  with  $\text{X} = \text{N}_3^-$ ,  $\text{CN}^-$ ,  $\text{ClO}_4^-$ , or  $\text{NO}_3^-$  were prepared via an ion-exchange reaction from  $[\text{MPy}]^+[\text{I}]^-$  and a counter anion [89]. Mixtures of energetic salts were prepared by dissolving the salts in 2-HEH in order to obtain high exclusion properties. The physical and chemical properties of the energetic salt mixtures such as decomposition temperature, density, viscosity, and decomposition energy were evaluated in order to determine their possible usefulness as liquid rocket fuels. The ignition delay times of the energetic salt mixtures with  $\text{H}_2\text{O}_2$  as an oxidizer were 135–167 ms. The properties of the synthesized energetic salts were predicted by Gaussian 09 computational G2 methods.

## 2.8 ILs Derived from Azepanes

The seven-member alicyclic secondary amine, azepane, has been used as starting material for the synthesis of RTILs. Such transformations of this co-product of diamine production processes, generated in large amounts in the polyamide industry, would mitigate its disposal, which usually involves combustion, and convert it to a useful product. Reaction of azepane with 1-bromoalkanes or 1-bromoalkoxyalkanes produced the corresponding tertiary amines with good selectivity; further quaternization reactions with the appropriate methylating agents yielded quaternary azepanium salts:  $[\text{Rmazp}]\text{X}$  ( $\text{R} = \text{alkyl or alkoxyalkyl}$ ;  $\text{X}^- = \text{I}^-$ ),  $[\text{CF}_3\text{COO}]^-$ , or  $[\text{OTf}]^-$  ( $\text{Tf} = \text{trifluoromethylsulfonyl}$ ) [90]. Analogous  $[\text{NTf}_2]^-$  salts have also been produced by metathetic reactions. Liquid temperature ranges were significantly affected by the nature of the anion and the substituents on the azepanium cation core, e.g.  $[\text{CF}_3\text{COO}]^-$  or  $[\text{OTf}]^-$  salts based on cations with alkyl substitution were solids whereas those with alkoxyalkyl substitution were liquid at ambient temperature. The presence of ether linkages in the cationic side chains caused a marked decrease in viscosities and an increase in conductivities.

## 2.9 ILs Derived from Hydrazines

*N,N*-Dimethylhydrazinium DCA and nitrocyanamide ILs were prepared by quaternization of *N,N*-dimethylhydrazine with alkyl halides followed by metathesis reactions with silver DCA or silver nitrocyanamide [91]. Spot plate tests with WFNA as the oxidizer showed that the 14 new *N,N*-dimethylhydrazinium salts were hypergolic with ignition delay times ranging from 22 to 1642 ms.

Enthalpies of formation ( $\Delta H_f$ ) of some EILs were predicted from quantum mechanical energies of molecules using an atomization approach [83]. The enthalpies of formation of *N,N*-dimethylhydrazinium EILs were predicted by a G2 procedure. It was found that the cyanomethyl group on *N,N*-dimethylhydrazinium-based system led to higher enthalpies of formation and increased the efficiency of the propellant.

Hypergolic fuels based on *N,N,N*-trimethylhydrazinium iodide ( $[\text{TMH}]^+[\text{I}]^-$ ) were synthesized by nucleophilic substitution and characterized by IR and  $^1\text{H}$ -NMR spectroscopy and GC-MS [84]. The hypergolic chemicals  $[\text{TMH}]^+[\text{X}]^-$  ( $\text{X} = \text{CN}^-$ ,  $\text{N}_3^-$ ,  $\text{NO}_3^-$ ,  $\text{NO}_2^-$ ,  $\text{ClO}_4^-$ , or  $\text{AlCl}_4^-$ ) were prepared via ion exchange reactions from  $[\text{TMH}]^+[\text{I}]^-$  and  $[\text{EMT}]^+[\text{I}]^-$ , respectively. The salts were dissolved in 2-HEH and decomposition temperature, density, viscosity, and decomposition energy were evaluated to determine their suitability for use as liquid rocket fuels. The ignition delay time of the mixture of hypergolic chemicals with  $[\text{TMH}]^+[\text{N}_3]^-$  and  $[\text{TMH}]^+[\text{CN}]^-$  using HTP as an oxidizer was 56 and 97 ms, respectively.

## 3 Anions for ILs

Many ILs described in the literature have inorganic, non-oxidizing anions such as tetrafluoroborate, hexafluorophosphate, trifluoromethylsulfonate ( $[\text{CF}_3\text{SO}_3]^-$ ), or bis-(trifluoromethylsulfonyl)imide. Because these inert ILs are only of academic interest, they are not included in this book. They may be used as intermediates by exchanging the inert anions with oxidizing anions.

### 3.1 ILs with DCA Anions

The chemical literature continues to describe the  $(\text{NC})_2\text{N}^-$  anion as dicyanamide, the same name as the parent acid. This is acceptable, as long as the word “anion” is carried along with it. It seems more reasonable to describe this anion as dicyanamidate, but this nomenclature has not yet taken hold. An alternate name, dicyanoamidate, is rarely found. The common abbreviation for dicyanamidate is dca or DCA.

A convenient source of DCA anions is in the form of calcium or barium dicyanamidate. Hypergolic ILs based on DCA anions are preferred because both the cation and the anion have fuel value.

Dicyanamide anions provide a combustible organic structure, and produce ILs with low viscosities and a wide liquidus range. The book *High-Energy-Density Fuels for Advanced Propulsion* contains a subsection on hypergolic ILs based on DCA anions [18]. All the liquid DCA salts of various imidazolium cations are hypergolic with inhibited red-fuming nitric acid (IRFNA) or WFNA [92]. However, the ignition delays were found to be between 170 and 670 ms, which is far from the required ignition delay time of <5 ms for a safe ignition. For comparison, the ignition delay time of hydrazine with RFNA is 4.8 ms. Importantly, the results showed that the DCA anions may play a key role in the ignition process, whereas the unsaturated substituents have less impact on the ignition delay time. Although the ignition of these DCA-based ILs with WFNA was not rapid, this work, for the first time, reported on the hypergolic properties of DCA salts and provided a new path for IL-based non-toxic hypergolic fuels. Ammonium and hydrazinium salts of DCA are unstable and have a tendency to rearrange to *N*-cyanoguanidine or cyclize to guanazole [93].

### 3.1.1 Reactions of ILs Containing DCA Anions

Understanding the ignition reactions for hypergolic propellants is an important step in developing a complete reaction model that can be used in rocket engine design and optimizing the composition of oxidizer/fuel combinations. An experimental study of the hypergolic reaction of sodium DCA with nitric acid was conducted to investigate reaction mechanisms for hypergolic ignition of this family of ILs [94]. Sodium DCA was used to simplify contributions to products from the cation of the fuel. Gas-phase reaction products were studied using microprobe sampling and MS analysis. In addition, a chemical assay was used to test for the presence of dinitrobiuret, the key intermediate in the proposed mechanism. Most of the results from the study supported a proposed mechanism, but there was no direct evidence for dinitrobiuret.

Four ILs, with a formula of  $[R(H_3C)_2NCH_2CH_2N_3][N(CN)_2]$  ( $R$  = ethyl, *n*-butyl, *n*-hexyl, and *n*-octyl) were synthesized through a metathesis reaction of quaternized *N,N*-dimethyl-2-azidoethylamine (DMAZ) with a different alkyl-chain length from that of silver DCA [95]. The density, dynamic viscosity, and thermal properties of these ILs were measured over a wide temperature range and the effect of the alkyl-chain length was examined. The density decreased, while dynamic viscosity and molar heat capacity increased with the increasing number of carbon atoms in the alkyl chain. The density showed a linear decrease with temperature, and the dynamic viscosity decreased with temperature according to the VFT equation. No melting points were found for these four ILs, except for glass-transition temperatures from 171 to 182 K (−102 to −91 °C). The decomposition temperatures of these four ILs ranged from 514 to 515 K (241–242 °C), independent of the alkyl-chain length.

In order to better understand the reaction dynamics of IL fuels containing DCA anions, MD simulation calculations were performed for two predicted intermediate compounds in nitric acid/DCA-based IL combustion, i.e. protonated DCA (DCAH) and

nitro-dicyanamide-carbonyl (NDC) [96]. Calculations were performed using a ReaxFF reactive force field model. Single-component simulations showed that neat NDC undergoes exothermic decomposition and ignition. Simulations with  $\text{HNO}_3$  were performed at both low and high densities to investigate the reaction in a dense vapor and liquid phase, respectively. Both DCAH and NDC react hypergolically with  $\text{HNO}_3$ , and increased density led to shorter times for the onset of thermal runaway. Contrary to a mechanism proposed by others for DCA combustion, neither DCAH nor NDC was converted to 1,5-dinitrobiuret before thermal runaway. See also [97–106].

Both the DCA anion,  $\text{N}(\text{CN})_2^-$ ,  $\text{DCA}^-$ , and dicyanoborohydride anion,  $\text{BH}_2(\text{CN})_2^-$ ,  $\text{DCBH}^-$ , have the desirable property of imparting hypergolicity to IL fuels. The question remained which of the two was more suited for this task. Direct quantum mechanical dynamics simulations of the reaction of  $\text{HNO}_3$  with  $\text{DCA}^-$  and  $\text{DCBH}^-$  were performed in an attempt to elucidate the primary and secondary reactions in the two reaction systems [107]. Guided by trajectory results, reaction coordinates and potential energy diagrams were mapped out for the oxidation of  $\text{DCA}^-$  and  $\text{DCBH}^-$  by one and two  $\text{HNO}_3$  molecules, respectively, in the gas-phase and condensed-phase ILs. The oxidation of  $\text{DCA}^-$  by  $\text{HNO}_3$  is initiated by proton transfer. The most important pathway leads to the formation of  $\text{O}_2\text{N}-\text{NHC}(\text{O})\text{NCN}^-$ , and the latter reacts with a second  $\text{HNO}_3$  to produce  $\text{O}_2\text{N}-\text{NHC}(\text{O})\text{NC}(\text{O})\text{NH}-\text{NO}_2^-$  ( $\text{DNB}^-$ ). The oxidation of  $\text{DCBH}^-$  by  $\text{HNO}_3$  may follow a similar mechanism to that of  $\text{DCA}^-$ . The theoretical results indicated that the formation of  $\text{DNB}^-$  is exclusively important in the oxidation of  $\text{DCA}^-$ , whereas the same type of reaction is a minor channel in the oxidation of  $\text{DCBH}^-$ . The combination of fast reaction rate constants, large exothermicities of  $\text{H}_2$  elimination, the high heat of combustion of the  $\text{H}_2$  product, and the low viscosity of the  $\text{DCBH}^-$  ILs have resulted in a shortened ignition delay time and enhanced pre-ignition performance of  $\text{DCBH}^-$  over  $\text{DCA}^-$ . Kinetics modeling has simulated the distinctive pre-ignition chemistry of  $\text{DCBH}^-$  and  $\text{DCA}^-$  and explained the different  $\text{HNO}_3$  oxidation kinetics of the two ILs.

A new strategy of cationic functionalization was developed by introducing the energetic nitrate (nitroxyl) group into the cationic units of ILs [108]. Interestingly, the introduction of oxygen-rich nitrate groups into the cationic structure of 12 ILs significantly improved the combustion performance of DCA hypergolic ILs. Ignition delays with WFNA were between 62 and 26 ms. The densities of these ILs were in the range of 1.22–1.39 g/cm<sup>3</sup>, which is much higher than that of UDMH (0.79 g/cm<sup>3</sup>).

### 3.1.2 Thermal Decomposition of ILs with DCA Anions

In an attempt to better understand decomposition mechanisms of  $\text{Emim}^+\text{DCA}^-$  and  $\text{EMmim}^+\text{DCA}^-$ , quasi-classical, direct-dynamics trajectories were calculated by quantum mechanical computational methods [109]. The trajectories showed many dissociation paths for these two ILs. Using trajectory results as a guide, structures of transition states and products that might be important for decomposition of these two

compounds were determined using DFT calculations. On the basis of modeling, initial decomposition paths for energized  $\text{Emim}^+\text{DCA}^-$  correspond to formation of an *N*-heterocyclic carbene and acid pair via transfer of the C2 proton of  $\text{Emim}^+$  to  $\text{DCA}^-$ , and evolution of methylimidazole and ethylimidazole via  $\text{S}_{\text{N}}2$  alkyl abstraction by  $\text{DCA}^-$ . Similar decomposition paths were identified for energized  $\text{EMmim}^+\text{DCA}^-$ , except that the reactivity of C2 of the imidazolium cation was significantly reduced upon substitution of a methyl group for a hydrogen atom at this position.

A droplet of 1-methyl-4-amino-1,2,4-triazolium dicyanamide ( $[\text{MAT}][\text{DCA}]$ ) was acoustically levitated in argon and heated to successively higher temperatures by a carbon dioxide laser [110]. At each temperature, *in situ* Fourier transform infrared (FTIR), Raman, and UV-visible spectra were recorded. The droplet became increasingly yellow before exploding at 400 K to produce a brown foam-like substance and dense smoke. The foam was subsequently studied *ex situ* by X-ray photoelectron and IR diffuse-reflectance spectroscopy, and elemental analysis. The combined spectroscopic analyses suggested that the foam was formed by linking two or more melamine molecules to yield a combination of melem, melon, and possibly graphitic carbon nitride. At least 37% of the  $[\text{MAT}][\text{DCA}]$  liquid was transformed into the stable, solid-state foam, which would be problematic for the use of such an IL-based hypergolic fuel in rocket engines because it might clog the injector orifices.  $[\text{Bmim}][\text{DCA}]$  did not explode and form this type of foam, even at temperatures of up to 430 K.

### 3.2 ILs with Nitrocyanamide Anions

The nitrocyanamide anion ( $[\text{N}(\text{NO}_2)(\text{CN})]^-$ ) is a hybrid between the  $\text{DCA}^-$  anion  $\text{N}(\text{CN})_2^-$  and the dinitramide anion  $\text{N}(\text{NO}_2)_2^-$  [111]. ILs with the nitrocyanamide anion are of interest both as ingredients for monopropellants or explosives and as hypergolic fuels with IRFNA or WFNA. Nitrocyanamide ILs with substituted imidazolium, guanidinium, and tetrazolium cations have been synthesized and characterized [112]. Aminoguanidinium nitrocyanamide crystallized in the triclinic system  $P\bar{1}$ . The results obtained from theoretical calculations based on aminoguanidiniumnitrocyanamide were consistent with single-crystal structure data. These ILs exhibit desirable physicochemical properties, such as low melting points, good thermal stability, and low impact sensitivity. Their energetic performances, including enthalpies of formation, detonation pressures, and detonation velocities, were studied by a combination of theoretical and empirical calculations. The ILs have wide liquid ranges and low viscosities. They were shown to be promising candidates as hypergolic ILs by performing ignition tests with 100%  $\text{HNO}_3$ .

Nine EILs were synthesized by anion exchange reactions between substituted imidazolium, guanidinium, or tetrazolium halides and silver nitrocyanamide ( $\text{Ag}[\text{N}(\text{CN})(\text{NO}_2)]$ ) in methanol. All of the resultant ILs were liquids at room

temperature and had desirable physicochemical properties, such as low melting points ( $m.p. < 183\text{ K} = < -90^\circ\text{C}$ ), good thermal stability ( $T_{\text{dec}} > 523\text{ K} = > 250^\circ\text{C}$ ), low viscosities ( $< 25\text{ mPa s}$ ), and good detonation performance. The ignition delay times of these ILs with WFNA were between 46 and 78 ms, similar to those of [Bmim][N(CN)<sub>2</sub>] (ignition delay = 47 ms). However, guanidinium or tetrazolium nitrocyanoamide ILs were not hypergolic with WFNA.

### 3.3 ILs with Boron-Containing Anions

A wide range of ILs with boron-containing anions have been tested as hypergolic fuels. Many of these compounds have very short ignition delays when they come in contact with WFNA. The boron-containing anions include  $\text{BH}_4^-$ ,  $\text{Al}(\text{BH}_4)_4^-$ ,  $\text{BH}_3\text{CN}^-$ ,  $\text{BH}_2(\text{CN})_2^-$ ,  $\text{BH}_2\text{BH}_3\text{CN}^-$ ,  $\text{BH}_3\text{CNBH}_2\text{CN}^-$ , and  $\text{PH}_2\text{B}_2\text{H}_6^-$ . Additional boron-containing anions are derived from the decaborate anion  $\text{B}_{10}\text{H}_{12}^{2-}$  and its adduct with ammonia,  $\text{B}_{10}\text{H}_{11}\text{NH}_3^-$ .

The presence of B—H bonds in the anion promotes the hypergolicity of ILs, while the introduction of intrinsically electron-rich groups (azide, allyl, propynyl, and B—H bonds) into the heterocyclic ring cation can efficiently shorten the ignition delay time of the ILs.

#### 3.3.1 Tetrahydroborate Anions

Lithium borotetrahydride ( $\text{LiBH}_4$ ) forms adducts with substituted tetrazoles such as 1,5-dimethyltetrazole or 1,5-dimethyltetrazole [113]. Although both complexes are solids at ambient temperature, the goal was to solvate  $\text{LiBH}_4$  at a high mol ratio and the general presence of multiple bonding modes might aid in liquefying these systems.

#### 3.3.2 Dicyanoborohydride Anions

Both the dicyanoamide anion,  $\text{N}(\text{CN})_2^-$ ,  $\text{DCA}^-$ , and the dicyanoborohydride anion,  $\text{BH}_2(\text{CN})_2^-$ ,  $\text{DCBH}^-$ , have the desirable property of imparting hypergolicity to IL fuels. The question remained which of the two was more suited for this task. Direct quantum mechanical dynamics simulations of the reaction of  $\text{HNO}_3$  with  $\text{DCA}^-$  and  $\text{DCBH}^-$  were performed in an attempt to elucidate the primary and secondary reactions in the two reaction systems [107]. Guided by trajectory results, reaction coordinates and potential energy diagrams were mapped out for the oxidation of  $\text{DCBH}^-$  by one and two  $\text{HNO}_3$  molecules, respectively, in the gas-phase and condensed-phase ILs. The oxidation of  $\text{DCBH}^-$  by  $\text{HNO}_3$  may follow a similar mechanism to that of  $\text{DCA}^-$ , producing two analog products:  $\text{O}_2\text{N—NHC}(\text{O})\text{BH}_2\text{CN}^-$  and  $\text{O}_2\text{N—NHC}(\text{O})\text{BH}_2\text{C}(\text{O})\text{NH—NO}_2^-$ . Theoretical calculations supported the enhanced pre-ignition performance of  $\text{DCBH}^-$  over  $\text{DCA}^-$  with WFNA. The combination of fast

reaction rate constants, large exothermicities of  $\text{H}_2$  elimination, the high heat of combustion of the  $\text{H}_2$  product, and the low viscosity of the  $\text{DCBH}^-$  ILs have resulted in a shortened ignition delay time and enhanced pre-ignition performance of  $\text{DCBH}^-$  over  $\text{DCA}^-$ .

The hypergolic ignition process of eight ILs with  $[\text{BH}_3(\text{CN})\text{BH}_2(\text{CN})]^-$  anions with WFNA was experimentally investigated by a droplet test method and safe-distance microscope high-speed photography techniques [114, 115]. Results showed that the hypergolic ignition process of these ILs was of a completely different 3-stage nature. An ultra-fast hypergolic ignition delay ( $<5$  ms) was observed for this family of ILs, based on “Coulomb explosion”-like behavior, in terms of the fast and vigorous ejection of liquid spikes that protruded from the mixing layer. The Coulomb explosion delay time was correlated with the side-alkyl functional group in the cation. In the second stage, liquid spikes that were ejected into the oxidizer pool significantly increased the reactive surface area underneath the liquid surface. As a consequence, local temperature increased and gas-phase intermediate product and oxidizer/fuel vapor accumulated due to the continuous liquid-phase reaction underneath the surface. The ignition delay time decreased with the increase of unsaturation index of the heterocyclic core in the cation. The enthalpies of formation of the ILs for different cation structures were correlated with ignition delay time, which represented both the fuel structure chemistry and the Coulomb explosion-enhanced mixing effect on the overall reactivity of this diffusive system.

Introduction of the cyano group into the anions of borane-based hypergolic fuels can greatly reinforce the hydrolytic stability [116, 117]. A 1-allylimidazole cyano-borane complex had some attractive properties such as water immiscibility and good hydrolytic stability, high density, good thermal stability ( $T_{\text{dec}} = 466 \text{ K} = 193^\circ\text{C}$ , onset), high calculated density impulse, ultra-short ignition delay time (WFNA, 3 ms), and low viscosity (8.4 mPa s).

*In situ* IR spectroscopy techniques and TGA-MS were used to characterize the reactivity of  $\text{Bmim}^+\text{DCBH}^-$ , in comparison to the well-characterized  $\text{Bmim}^+\text{DCA}^-$  IL [118]. TGA measurements determined the enthalpy of vaporization ( $\Delta H_{\text{vap}}$ ) to be  $112.7 \pm 12.3 \text{ kJ/mol}$  at 298 K. A rapid-scan FTIR spectrometer was used to track the appearance and disappearance of species in the hypergolic reactions of  $\text{Bmim}^+\text{DCBH}^-$  and  $\text{Bmim}^+\text{DCA}^-$  with WFNA, and in the thermal decomposition of these EILs. Experimental results indicated that the hypergolic reaction of  $\text{Bmim}^+\text{DCBH}^-$  with WFNA generated both common and unique intermediates as compared to previous  $\text{Bmim}^+\text{DCA}^- + \text{WFNA}$  investigations. Nitrous oxide  $\text{N}_2\text{O}$  was generated during both hypergolic reactions indicating that it may play a role in the hypergolic ignition process,  $\text{NO}_2$  was generated in significantly higher concentrations for  $\text{Bmim}^+\text{DCBH}^-$  than for  $\text{Bmim}^+\text{DCA}^-$ ,  $\text{CO}_2$  was only generated for  $\text{Bmim}^+\text{DCA}^-$ , and hydrogen cyanide (HCN) was only generated during thermal decomposition and hypergolic ignition of  $\text{Bmim}^+\text{DCBH}^-$ .

### 3.3.3 Cyclic Boranate Anions

ILs can be formed from heterocyclic amine cations and polyhedral borane anions. The synthesis, structure, and physical properties of nitrogen heterocyclic salts of the polyhedral borane anions (closo-decaborate  $[B_{10}H_{10}]^{2-}$ , closo-dodecaborate  $[B_{12}H_{12}]^{2-}$ , carba-closo-dodecaborate  $[CB_{11}H_{12}]^{-}$ , and their derivatives), and their potential application as ILs and energetic materials, have been reviewed [119].

A series of borohydride cluster-based ILs with excellent hydrolytic and thermal stabilities ( $T_d > 200^\circ\text{C}$ ) and high density ( $1.18\text{ g/cm}^3$ ) were prepared [120]. Upon contact with WFNA or  $N_2O_4$ , these ILs had ultra-short ignition delay times (as short as 1 ms).

### 3.3.4 Substituted Boranate Anions

A series of cyanotetrazolylborohydride (CTB) anion-based ILs was synthesized by a straightforward *N*-hydroboration of tetrazole followed by a salt metathetical reaction [121]. These ILs exhibited remarkably low viscosity ( $<20\text{ mPa}\cdot\text{s}$ ), high density ( $>1.1\text{ g/cm}^3$ ), and ultra-short ignition delay time (as short as 1.4 ms) upon contact with WFNA.

### 3.3.5 Tetrakis(tetrahydroborate)aluminate Anions

ILs with  $Al(BH_4)_4$  anions have high reactivity with oxidizers, but lack other properties to make them practical as liquid propellants. In an attempt to lower the viscosity, neutral  $Al(BH_4)_3$  was mixed with an IL containing the cyanoborohydride anion [113]. ILs with the  $[NCBH_3]^{-}$  anion by itself generally possess very low viscosities ( $\sim 20\text{ cPs}$ ). It was anticipated that the combination of  $[NCBH_3]^{-}$  with  $Al(BH_4)_3$  would produce a new anion of the formula  $[Al(BH_4)_3NCBH_3]^{-}$ . There were indications of a mixed borohydride/cyanoborohydride aluminum compound with a coordination number of seven. Unfortunately, neither the cyanoborohydride approach nor the pure tetrakis/tetrahydroborate aluminate ILs discovered possessed the desirable physical properties for a suitable propellant.

## 3.4 ILs with Anions Derived from Heterocyclic Amines

Surprisingly, while most azotetrazolates exhibit melting points in excess of 423 K ( $160^\circ\text{C}$ ), bis(1-butyl-3-methyl-imidazolium) 5,5'-azotetrazolate is an RTIL with a melting point of 270 K ( $3^\circ\text{C}$ ), [122], similar to its 3,5-dinitrotetrazolate analog which melts at 308 K ( $35^\circ\text{C}$ ), as described in [49].

Twenty-eight energetic salts with tetramethyl-, tetraethyl-, and tetrabutylammonium and 1-butyl-3-methylimidazolium cations paired with 3,5-dinitro-1,2,4-triazolate, 4-nitro-1,2,3-triazolate, 2,4-dinitroimidazolate, 4,5-dinitroimidazolate, 4,5-dicyanoimidazolate, 4-nitroimidazolate, and tetrazolate anions have been pre-

pared and characterized by using DSC, TGA, and single-crystal XRD in order to study the effects of cation and anion type on the physicochemical properties of the resulting crystalline salts or ILs [50]. ILs (defined as having a m.p.  $< 373\text{ K} = < 100^\circ\text{C}$ ) were obtained with all combinations of the 1-butyl-3-methylimidazolium cation ( $\text{C4mim}^+$ ) and the heterocyclic azolate anions studied, and with several combinations of tetraethyl or tetrabutylammonium cations and the azolate anions. The  $\text{C4mim}^+$  azolates were liquids at room temperature exhibiting wide liquid ranges and forming glasses on cooling with glass-transition temperatures in the range of  $220\text{--}191\text{ K}$  ( $-53$  to  $-82^\circ\text{C}$ ), except for the 3,5-dinitro-1,2,4-triazolate salt (m.p.  $306\text{ K} = 33^\circ\text{C}$ ).

The dinitromethanide  $(\text{NO}_2)_2\text{CH}^-$  anion proved to be a useful component of RTILs with substituted imidazolium cations [123]. Delocalization of both the  $(\text{NO}_2)_2\text{CH}^-$  anion and dimethylimidazolium cation was found from single-crystal structure data. Their impact sensitivities were determined and they were found to be insensitive ( $>40\text{ J}$ ).

## 4 Physical Properties of ILs

Physical properties of specific ILs are interspersed as examples in the following sections under their parent amine from which the salts were derived. The most important property of an IL is its melting point (freezing point if it is a liquid at room temperature). Other properties of interest for rocket propellant chemists are the enthalpy of formation and the density. The following sections discuss the physical properties of ILs in general, often with examples for more than one compound. This is why these publications could not be cited at just one location in this chapter.

### 4.1 Melting Points and Phase Changes of ILs

ILs exhibit low-melting-point behavior as a result of disrupting the attractive ion–ion interactions in conventional salts by introducing structural “buffer-zones” of van der Waals-only regions into the ions, principally cations, which suppress crystallization, leading to the formation of either glasses on cooling, or low-lattice energy solids, typical opportunities for both polymorphism and plastic crystal formation. Anions often grouped with these cations are nitrate ( $\text{NO}_3^-$ ), perchlorate ( $\text{ClO}_4^-$ ), and the DCA anion  $\text{N}(\text{CN})_2^-$ .

The liquidus ranges exhibited by ILs can be much greater than those of common molecular solvents. Water, for example, has a liquidus range of  $273\text{--}373\text{ K}$  ( $0\text{--}100^\circ\text{C}$ ). The lower temperature limit of ILs, solidification (either crystallization or glassification), is governed by the structure and interactions between the ions. Phase transitions of ILs are not sharp endotherms on the DSC thermograms, but diffuse, wide peaks extending over a range of 10 degrees. The heat of fusion can also be derived

from the DSC thermograms and is used along with the peak temperature of the phase-change DSC to characterize the compounds. ILs, consisting of totally ionized components and displaying relatively weak ion–ion pairing (in comparison to molten salts), have little or no measurable vapor pressure. In contrast to molecular solvents, the upper liquidus limit for ILs is usually that of thermal decomposition rather than vaporization.

The melting points of organic salts are influenced by the symmetry of the molecule, the flexibility of the alkyl or aryl substituents, and the accessibility of the charges. ILs do not have sharp freezing points, but undergo a gradual transition to a glassy, highly viscous state. The ILs are best characterized by their glass-transition temperature ( $T_g$ ). There are different definitions of the glass-transition temperature. According to one definition,  $T_g$  is the temperature at which the shear viscosity reaches  $10^{12}$  Pa s. Another states that it is the temperature at which the characteristic molecular relaxation time reaches  $\tau_g = 100$  s.

The physical and chemical properties of ILs can be tailored to meet certain application criteria. In most cases, this is achieved by the appropriate selection of the cation and anion pair or by changing the substituents on one or both of the heterocyclic amine rings. A simple chemometric model was used to tune the melting and freezing points of a model IL, [Hmim][NO<sub>3</sub>] [124].

## 4.2 Densities of ILs

Volume parameters for RTILs and salts were developed for 59 of the most common imidazolium-, pyridinium-, pyrrolidinium-, tetra-alkylammonium-, and phosphonium-based RTILs [125]. The mean absolute deviation (MAD) of the densities was  $0.007 \text{ g/cm}^3$ ; for 35 imidazolium-based room-temperature salts, it was  $0.020 \text{ g/cm}^3$ ; and for 150 energetic salts, it was  $0.035 \text{ g/cm}^3$ . The experimental density ( $Y$ ) for an alkylated imidazolium- or pyridinium-based RTIL is approximately proportional to its calculated density ( $X$ ) in the solid state. This method was later extended over a wider range of temperatures and pressures [126].

Although numerous different ILs exist, even basic physical-property data, such as the density and melting point, exist only for relatively few. Derivation of melting-point QSPRs for EILs would therefore greatly aid in the molecular design of new energetic compounds. Samples of ILs based on 1-substituted 4-amino-1,2,4-triazolium bromide and nitrate salts were synthesized and their melting points and densities measured [127]. The molecular geometries of the cations of the ILs were optimized using *ab initio* quantum chemical methods. Melting-point QSPRs were then derived from molecular orbital, thermodynamic, and electrostatic potential (ESP) descriptors, and good correlations with experimental data were achieved. The correlation coefficients for 3-parameter melting-point QSPRs and for 1-parameter density QSPRs exceeded 0.9. Although some of the descriptors that appeared in the QSPRs were designed to describe

chemical reactions, it was inferred that they served in this study only to quantify interactions between the cation and anion.

The liquid density of imidazolium-based ILs was estimated using a combined method that included an artificial neural network and a simple group-contribution method [128]. A total of 1736 data points of density at several temperatures and pressures, corresponding to 131 ILs, was used to train the neural network. The molar mass and the structure of the molecule were given as input variables. New values of density as a function of temperature and pressure for 33 other ILs were predicted, and the results were compared to experimental data from the literature. The results showed that the chosen artificial neural network and the group contribution method represent a viable alternative for the estimation of the liquid density of imidazolium-based ILs, with acceptable accuracy for a wide range of temperatures and pressures (258–393K and 99–206940 kPa, respectively).

A group-contribution model of the  $p$ - $\rho$ - $T$  relation based on a large amount of data by different authors for 1- $C_n$ -3-methylimidazolium-based ILs with  $n = 2, 4$ , and 6, and with the  $N(CN)_2$  anions, describes the dependence of density, isobaric expansivity, and isothermal compressibility on temperature, pressure, the length of the alkyl side chain of the cation, and the anion [129]. This makes it possible to obtain the most reliable values of the density and assess which sets of data can be considered more accurate than others.

### 4.3 Velocity of Sound in ILs

The velocity of sound is an important physical property of any propellant and can be used to derive other properties like adiabatic compressibility or thermal conductivity. A database for the velocity of sound of pure ILs, created by collecting experimental data from literature covering the period 2005–2013, was used to study the effects of temperature and the alkyl-chain length on the velocity of sound and a second-order, corresponding-states, group-contribution computational method was developed to estimate the velocity of sound of new ILs [130]. The velocity of sound can be used to determine the thermal conductivity of ILs based on the Bridgman theory. The calculated values of thermal conductivity showed good agreement with the experimental data.

A review of the literature data on the velocity of sound and ultrasound absorption in pure ILs included an analysis of experimental methods described in the literature to determine the velocity of sound in ILs as a function of temperature and pressure, and the relevance of ultrasound absorption in acoustic investigations [131]. A relation between ion structures and velocities of sound would be useful for predicting the velocity of sound in yet undiscovered ILs.

#### 4.4 Vapor Pressures of ILs

The vapor pressure of ILs is usually below the level at which it can be measured. This is very desirable and is one of the reasons why ILs have received so much attention as potential rocket propellants as they are without respiration toxicity or vapor flammability hazard.

Isolated ion pairs of a reactive hypergolic IL,  $\text{Bmim}^+\text{DCA}^-$ , were generated by vaporizing IL sub-micrometer aerosol particles [132]. The vaporized species were investigated by dissociative ionization with tunable VUV light, exhibiting clear intact cations. Mass spectra of ion-pair vapor from an effusive source of the hypergolic IL showed substantial reactive decomposition due to the internal energy of the molecules emanating from the source. The method of IL sub-micrometer aerosol particle vaporization for reactive ILs such as hypergolic species is a convenient, thermally “cooler” source of isolated intact ion pairs in the gas phase compared to effusive sources.

A neutral, intact ion pair of a vaporized IL,  $\text{Bmim}^+\text{TCM}^-$  was observed in a vacuum chamber using tunable VUV photonionization (PI)-time-of-flight (TOF) mass spectrometry (MS) [71]. The ionization potential (IP) for the ion pair was experimentally determined to be  $6.6 \pm 0.5$  eV. TGA determined the  $\Delta H_{\text{vap}}$  to be  $298 \text{ K} = 143.5 \pm 6.2 \text{ kJ/mol}$ . Vaporization of  $\text{Bmim}^+\text{TCM}^-$  as ion pairs was the dominant mechanism for mass loss under the experimental conditions for VUV PI-TOFMS ( $T = 433 \text{ K}$ ).

Methods for vaporizing ILs with very low vapor pressures were developed using HAN, HEH, ammonium nitrate (AN), and mixtures of these compounds [133]. Models were developed to understand the ionization processes of vaporized ionic mixtures.

#### 4.5 Viscosity of ILs

Ionic liquids are more viscous than most other organic solvents. The higher viscosity is caused by electrostatic attraction between the ions of different charge polarities.

The viscosity of imidazolium-based ILs with four different cations and three different anions was measured at pressures up to 126 MPa and at three temperatures (298, 323, and 343 K) [134]. The high-pressure viscosity of Emim, 1-*n*-hexyl-3-methylimidazolium (Hmim), and 1-*n*-decyl-3-methylimidazolium (Dmim) cations with a common anion, bis(trifluoromethylsulfonyl)imide Tf2N, was measured to determine the alkyl-chain-length effect of the cation. An increase in the alkyl-chain length increased the viscosity at elevated pressures. Dmim exhibited a larger non-linear increase with pressure over the shorter alkyl substituents. Anion effects were investigated with Hmim as a common cation and the anions Tf2N, hexafluorophosphate ( $\text{PF}_6$ ), and tetrafluoroborate ( $\text{BF}_4$ ).  $[\text{Hmim}][\text{PF}_6]$  had the highest viscosity and a very non-linear pressure dependence, even at relatively moderate pressures (of up to 30 MPa), similar to the results for  $[\text{Bmim}][\text{PF}_6]$ .

Melting temperatures, glass-transition temperatures, decomposition temperatures, heat capacities, and viscosities for a large series of pyridinium-based ILs were measured, with data for several imidazolium and quaternary ammonium salts included for comparison [135]. Many of these compounds did not crystallize, but formed glasses at temperatures between 188 and 223 K. Viscosities generally increased with the increasing number and length of alkyl substituents on the cation, with the pyridinium salts typically being slightly more viscous than the equivalent imidazolium compounds.

Density, viscosity, and surface tension data sets of 13 ILs formed by imidazolium, pyridinium, or pyrrolidinium cations paired with dicyanamidate, tetrafluoroborate, thiocyanate, methylsulfate, and trifluoroacetate anions were measured at temperatures between 293 and 363 K [136]. The effect of the IL-forming anion and cation on the physical properties was analyzed systematically. A longer alkyl chain in imidazolium-based ILs was associated with lower density, higher viscosity, and lower surface tension. Density of [C4mim][DCA],  $C_{10}H_{15}N_5$ , at 293.15 K and 100 kPa was  $1.064.4 \pm 0.008 \text{ g/cm}^3$ , and viscosity was  $0.0332 \pm 0.0009 \text{ Pa}\cdot\text{s}$ .

The investigation of the MD of ILs is vital for the fundamental understanding of their physical nature as well as for the successful engineering design in their applications. An in-depth rheological study of two ILs of different nature in a wide frequency and temperature range (up to the glass-transition point and beyond) was performed, utilizing techniques with an oversampling procedure and with adjustment of the instrument compliance [137].

The effect of azolate anion structure on the physical properties of four ILs, specifically on their glassy dynamics and ion interactions, was studied utilizing rheology, X-ray scattering, UV/vis absorption, and *ab initio* calculations [138]. Three of the ILs shared the same Bmim cation. The anions were tetrafluoroborate, 1-butyl-3-methylimidazolium 4-nitroimidazolate, and 1-butyl-3-methylimidazolium 5-aminotetrazolate. The peculiar rheological behavior for these ILs, which deviated from what was expected for molecular glass-formers, included high elasticity in the low-frequency zone and failure of time–temperature superposition. These peculiarities were attributed to specific interactions in the nitrogen-rich planar rings of azolate ILs. X-ray scattering measurements revealed a nanometer-ordered organization in azoliumazolates due to H-bond interactions. This conclusion was also supported by *ab initio* calculations.

In order to compare the viscosities of different ILs, it is possible to plot the logarithm of the viscosity versus the reciprocal absolute temperature normalized by the glass-transition temperature, as shown in Figure 2.

The viscosity of ILs can be lowered by adding graphene as a lubricant, thus improving ignition delays [139]. The viscosity of ILs can be reduced and the ignition delay can be improved by dilution with ethanol [140].

Experimental data for viscosity of 268 typical ILs from 215 literature references were compiled and critically evaluated and the effects of ionic molecular structures on the viscosity of ILs were presented [141]. Water and residual  $Cl^-$  have an effect on the

**Figure 2:** Viscosity versus  $T_g/T$  for the [Bmim]BF<sub>4</sub> (squares), [TMP]Tos (triangles), [Bmim]5AT (circles), and [Bmim]4Ni-lm (diamonds) ILs. The dashed straight line represents the Arrhenius model, and the solid curved line represents the VFT model.

viscosity of ILs. The parameters of the VFT equation for the temperature dependence of the viscosities of these ILs were reported.

Transport properties include thermal conductivity for heat transfer, viscosity for momentum transfer, and diffusion coefficient for mass transfer. The transport properties are important for all applications of ILs. High viscosity hinders the applications of some of the ILs. A review of the transport properties of pure ILs and mixtures of ILs with other compounds attempted to derive a correlation between the transport properties and the molecular structures [142].

ILs are known to have very high viscosities, which makes it difficult to pump and spray atomize them in a rocket combustion chamber. The rheological behavior of a fluid is an important property that has a distinct impact on its viscosity, mass transfer rates, and fluid dynamics. It is necessary to study the different rheograms and the viscoelastic properties of fluids. A review looked at imidazolium-based combinations of ILs and natural deep eutectic solvents, in terms of different H-bond donors (HBD) and H-bond acceptors (HBA), with different molar ratios of HBA:HBD; the rheological behaviors of these combinations at ambient-temperature conditions and higher temperatures were critically evaluated [143].

## 4.6 Surface Tension of ILs

The pendant drop method has been used for measuring the surface tension of pure ILs in the range of 278–333 K [144]. In addition, densities and thermal-expansion coefficients of these ILs were presented. The values of surface tension were between 25 and 48 mN/m and decreased with temperature. Although this study used ILs that are not useful as rocket propellants, the same method can be used to measure surface tensions of EILs.

Air-liquid interfacial tension data and density data were measured for two ILs with the 1- $C_n$ -3-methylimidazolium cation,  $n=2$  and 4, and the DCA anion at atmospheric pressure in the temperature range 278–356 K [145]. The density was measured using a buoyancy method. An analysis of the experimental density data, using a group-contribution model, performed for eight ILs with the 1- $C_n$ -3-methylimidazolium cation ( $n=2, 4, 6$ ), and the tetrafluoroborate, trifluoromethanesulfonate, and DCA anions, indicated that the uncertainty arising from impurities present in the sample was significant. The model is capable of providing predictions for pure imidazolium-based ILs with the  $\text{BF}_4^-$ ,  $\text{CF}_3\text{SO}_3^-$ , and  $\text{N}(\text{CN})_2^-$  anions.

## 4.7 Thermal Conductivities of ILs

Thermal conductivity of ILs is not as important for their use as rocket propellants as it is for their proposed use as thermal storage and heat transfer fluids. The thermal conductivities of ten ILs based on the anions  $\text{C}(\text{CN})_3^-$  (i.e. tricyanomethanide, TCM) and  $\text{B}(\text{CN})_4^-$  (tetracyanoborate), and a homologous series of the [alkyl-mim] $^+$  (1-alkyl-3-methylimidazolium) cations Emim $^+$  (ethyl), Bmim $^+$  (butyl), Hmim $^+$  (hexyl), Omim $^+$  (octyl), and Dmim $^+$  (decyl) were measured by a steady-state guarded parallel-plate instrument in the temperature range 283.15–353.15 K at atmospheric pressure [146]. The measured thermal conductivities of the ILs decreased with increasing temperature and increasing alkyl-chain length of the cation. Regarding the influence of the anion, somewhat smaller values were observed for the  $[\text{B}(\text{CN})_4]^-$ -based ILs than for the  $[\text{C}(\text{CN})_3]^-$ -based ILs carrying the same cation. A simple prediction method for the thermal conductivity of ILs using only information on the molar mass and the density was derived. By the combination of this approach with the temperature dependence of the density, an extended empirical correlation additionally describing the temperature dependence of the thermal conductivity of ILs was selected.

A database for the thermal conductivity of ILs was established by collecting experimental data from the literature covering the period 2007–2013, including 359 data points from 45 ILs, with the objective of studying the relationship between temperature or the alkyl-chain length of the cation and thermal conductivity [147]. A topological index method was proposed to estimate the thermal conductivity of ILs based on the collected data. The total average absolute deviation between the calcu-

lated and literature data was 2.3%. The topological index method guaranteed satisfactory precision with a simple form and can be easily expanded to new types of ILs.

ILs are very viscous and it is difficult to measure their thermal conductivity. In order to fill missing experimental data gaps, an estimation approach has been developed. A structure-interpolating approach was chosen, assigning contributions to thermal conductivity to the individual ions [148]. A total of 375 experimental data points for 39 ILs were used for the development. A detailed error analysis resulted in a combined experimental and predictive uncertainty of 7.96% for unknown ILs. A systematic screening of ILs based on their thermal conductivity is possible.

A simple, general, accurate, and easy-to-use correlation was developed for estimating the thermal conductivities of pure ILs over a wide range of temperatures at atmospheric pressure [149]. The objective was to develop a thermal conductivity correlation which does not require any other physical properties as input parameters, once a single thermal conductivity data point is available. A correlation has been proposed based on 378 thermal-conductivity temperature data points from 44 different IL types. The proposed correlation, in comparison to two well-known and commonly used group-contribution models and one literature correlation, showed much better accuracy with respect to experimental values.

ILs have been considered as replacement materials for halogenated heat transfer fluids. Thermal conductivity and heat capacity must be known for this application and would also be useful for rocket applications. The impact of electronic structure on the heat capacity was confirmed by DFT calculations [150]. The objective of this work was to assess the predictive capabilities of existing models for thermal conductivity and heat capacity, with further improvements based on more accurate investigated structure characterization and reparameterization using group-contribution methodology.

#### 4.8 Electrical Conductivities of ILs

Many ILs have been proposed as electrolytes for batteries and capacitors, and for this application they must have good electrical conductivities and/or dielectric constants. The electrical conductivities of ILs are of primary interest for their use as electrolytes, but are also needed for their use in electrospray colloid thrusters or in the design of electrolytic igniters for monopropellants.

#### 4.9 Thermodynamic Properties of ILs

A few examples of the thermodynamic properties of ILs are listed in this section. More thermophysical property data are listed in the sections for specific ILs. Thermophysical properties of 13 imidazole-derivative ILs were determined by DSC, but only one of those investigated would be of interest as a rocket propellant: [Bmim][DCA], CAS RN

[44824-52-1], is a potential hypergolic fuel for bipropellant engines [151]. It has a glass-transition temperature of 183 K (−90 °C) and a melting point of 267 K (−6 °C). The heat capacity at 298 K is 364.6 J mol<sup>−1</sup> K<sup>−1</sup> and the heat capacity function is

$$C_p = 0.197T + 305.81 \text{ J mol}^{-1} \text{ K}^{-1}.$$

Heat capacities of numerous other ILs were measured, but only few of those are of interest as rocket propellants. Nevertheless, the methods demonstrated for the measurement of heat capacities of these inert ILs can also be applied to EILs.

Heat capacities of five ILs were measured from 283.15 to 358.15 K. The  $C_p$  293.15-K estimated values were about 12% higher than the experimental values. The estimates suggested that heat capacities of ILs do not differ considerably from those typical for molecular liquids. The heats of solution of ILs in water, acetonitrile, and methanol were measured as a function of IL concentration [152].

Heat capacities for nine ILs have been determined with a “three-step” method using two different DSC devices. In addition, the heat capacities of these ILs have been studied by the modulated-temperature DSC method [153]. Heat capacities of nine ILs were measured from 293 to 358 K by using a heat flux DSC device [154].

A computational approach to the prediction of the heats of formation ( $\Delta H_f^\circ$ ) of solid-state energetic salts from electronic structure and volume-based thermodynamics (VBT) calculations used as its starting point reliable  $\Delta H_f^\circ$  data for energetic precursor molecules and ions [155]. An isodesmic crystal is a crystal in which all the bonds have the same electrostatic valency. The  $\Delta H_f^\circ$  of more complex energetic species such as substituted imidazole, 1,2,4-triazole, and tetrazole molecules and ions were calculated in this way and compared to experimental data.

Thermochemical and detonation parameters were calculated for the IL 1-ethyl-3-methyl-*H*-imidazolium perchlorate, [Emim][ClO<sub>4</sub>] and its associated solid [156]. The thermochemical values estimated included: lattice energy,  $U_{\text{POT}}([\text{Emim}][\text{ClO}_4])$  515 ± 67 kJ/mol (123 ± 16 kcal/mol); enthalpy of formation of the gaseous cation,  $\Delta H_f^\circ([\text{Emim}]^+(\text{G})) = +603 \text{ kJ/mol}$  (+144.2 kcal/mol) and anion,  $\Delta H_f^\circ([\text{ClO}_4]^{-}(\text{G})) = -277 \text{ kJ/mol}$  (−66.1 kcal/mol); enthalpy of formation of the solid salt,  $\Delta H_f^\circ([\text{Emim}][\text{ClO}_4](\text{S})) = -230 \pm 67 \text{ kJ/mol}$  (−55 ± 16 kcal/mol) and for the associated IL,  $\Delta H_f^\circ([\text{Emim}][\text{ClO}_4](\text{L})) = -218 \pm 67 \text{ kJ/mol}$  (−52 ± 16 kcal/mol) as well as the corresponding Gibbs energy terms:  $\Delta G_f^\circ([\text{Emim}][\text{ClO}_4](\text{S})) = +121 \pm 67 \text{ kJ/mol}$  (+29 ± 16 kcal/mol) and  $\Delta G^\circ([\text{Emim}][\text{ClO}_4](\text{L})) = +100 \pm 67 \text{ kJ/mol}$  (+24 ± 16 kcal/mol) and the associated standard absolute entropies, of the solid [Emim][ClO<sub>4</sub>],  $S^\circ_{298}([\text{Emim}][\text{ClO}_4](\text{S})) = 347 \pm 17 \text{ J} \cdot \text{K}^{-1} \cdot \text{mol}^{-1}$  (83 ± 4 cal · K<sup>−1</sup> · mol<sup>−1</sup>). Combustion and detonation parameters were predicted for [Emim][ClO<sub>4</sub>] in its (ionic) liquid form:  $I_{\text{sp}} = 228 \text{ s}$  (monopropellant), detonation velocity ( $V_D$ ) = 5466 m/s, detonation pressure ( $p_{\text{CJ}}$ ) = 99 kbar, and explosion temperature ( $T_{\text{ex}}$ ) = 2842 K.

On the basis of a database of thermodynamic data established for 53 ILs, at least five models that made use of constitutional descriptors gave pretty good predictions for the heats of combustion of ILs [157]. A model for predicting heats of combustion of

ILs has been developed using a multi-linear regression. The model obtained from a set of 40 molecules revealed a good fit with the values in the literature. The heat capacities of pyridinium and imidazolium ILs, including [C4Mim][DCA], can be extrapolated from measured data [158].

The heat of vaporization of *N*-butyl-*N*-methylpyrrolidinium bis(trifluorosulfonyl)imide was found to be  $\Delta H_{\text{vap}}(298.15\text{ K}) = 195 \pm 19\text{ kJ/mol}$ , that of [C4Mim][DCA] was  $\Delta H_{\text{vap}}(298.15\text{ K}) = 174 \pm 12\text{ kJ/mol}$ , and that of *N*-butyl-*N*-methylpyrrolidinium dicyanamide was  $\Delta H_{\text{vap}}(298.15\text{ K}) = 171 \pm 12\text{ kJ/mol}$  [159]. These experimental heats of vaporization, photo ion appearance energies, and *ab initio* calculations corroborate vaporization of these RTILs as intact cation–anion pairs.

A computational method for the prediction of the condensed phase (solid or liquid) heat of formation (HOF) of triazolium-based energetic ionic liquids (EILs) at 298 K was based on the influence of some specific elemental compositions of cations and anions as additive parts [160]. The reported HOF values of 57 different triazolium-based EILs were used to derive a new model. For 34 different triazolium-based EILs, where the outputs of quantum mechanical methods were available, the Root Mean Squared Error (RMSE) of the new model was 156 kJ/mol.

#### 4.10 Computational Modeling Studies of the Molecular Structures of ILs

In addition to experimental investigations for the development of ILs as rocket propellants and for other industrial applications, theoretical studies are aimed at understanding the interaction of ions in the melt that give these liquids their unique physical properties. It is hoped that once the theory of ILs is better understood, that more EILs with physical properties (viscosity) more aligned with conventional rocket propellants can be developed based on predictions from computer calculations (“designer ionic liquids”) and tailored to specific properties needed for a given application.

The thermophysical and transport properties of ILs were theoretically investigated by means of molecular simulation techniques [161–163]. Quantum calculations were used as a support tool to force field development work. The cations studied included imidazolium-, pyridinium-, and triazolium-based structures, with different inorganic anions such as hexafluorophosphate, nitrate, and perchlorate, and one organic anion, bis(trifluoromethanesulfonyl)imide. Force fields for a range of imidazolium-, pyridinium-, and triazolium-based ILs were developed and published. The static properties computed included gravimetric densities, volumetric expansivities, isothermal compressibilities, heat capacities, cohesive energy densities as well as the liquid structure. Analysis of the dynamic properties of IL systems was aimed at information on the rotational dynamics and transport properties such as self-diffusivity. Additional work was done comparing the structures of hydrazinium(1+) nitrate, methylhydrazinium nitrate, and 1,1-dimethylhydrazinium

nitrate, also in comparison to 2-hydroxyethylhydrazinium nitrate (HEHN) which has a very low melting point ( $<248\text{ K}$ ).

The overall objective of the *Design of Energetic Ionic Liquids* challenge project is to characterize, design, and develop ILs as new monopropellants [164]. A fundamental understanding of the (in)stability of ILs, the intrinsic nature of the short- and long-range structure and interactions between the component ions, and identification of the key steps in the initial stages of decomposition and combustion can be achieved by computational chemistry. A hierarchy of computational approaches has been employed to predict the performance of EILs as monopropellants and fuels [164]. This effort included atomistic, high-level quantum chemical methods applied to individual ions and ion clusters, condensed-phase atomistic MD simulations utilizing polarizable force fields, and mesoscale-level simulations of bulk ILs based upon multi-scale coarse-graining techniques.

Electronic structure modeling calculations have been performed on the tetrazolium cation with a variety of substituents [165]. DFT with the B3LYP functional, using the 6-311G(d,p) basis set was used to optimize geometries. Improved treatment of dynamic electron correlation was obtained using second-order perturbation theory based on the Møller-Plesset 2 (MP2) method. Heats of formation of the cation with different substituent groups were calculated using isodesmic reactions and Gaussian-2 calculations on the reactants. In the search of EILs, the cation was paired with oxygen-rich anions, such as  $\text{ClO}_4^-$ ,  $\text{NO}_3^-$ , or  $\text{N}(\text{NO}_2)_2^-$ , and these structures were optimized using both DFT and MP2. The reaction pathway may involve a proton transfer from the cation to the anion.

Synthesis and extensive experimental and crystallographic analysis of the properties of protonated ILs, including nitro-substituted 1-alkyl-3-H-imidazolium and 1-alkyl-2-methyl-3-H-imidazolium nitrate and picrate salts, was conducted as part of an investigation of physical and chemical properties directed towards the development of an understanding of the criteria needed to model and predict IL materials incorporating energetic moieties [166].

A computational approach to predict the thermodynamics for forming a variety of imidazolium-based salts and ILs from typical starting materials was based on calculating the gas-phase proton and methyl cation acidities of several protonating and methylating agents, as well as the proton and methyl cation affinities of many important methyl-, nitro- and cyano-substituted imidazoles [167]. These calculated proton and methyl cation affinities of neutrals and anions were used in conjunction with an empirical approach, based on molecular volumes, to estimate the lattice enthalpies and entropies of ILs. A thermodynamic cycle for salt formation can predict the likelihood of success to synthesize a variety of energetic salts including ones with potentially high energy densities. This was then applied to imidazoles (the cation to be formed) with alkyl, nitro, and cyano substituents.

Previous studies of ILs have focused on the decomposition of ion pairs, providing insight into the chemistry of their ignition as high-energy fuels. Beyond this, it has

been attempted to accurately describe larger systems beyond single anion–cation pairs. The fragment molecular orbital (FMO) method, which decomposes a large molecular system (e.g. a cluster, protein, liquid, zeolite, etc.) into small subunits (fragments) that are designed to both retain the high accuracy of the chosen quantum mechanical level of theory while greatly reducing the demands on computational time and resources, was used in studies of ion clusters. Two IL systems, 1,2,4-triazolium dinitramide and 4-amino-1,2,4-triazolium dinitramide, were studied using both *ab initio* MP2 and the MP2 implementation of the FMO method, with each ion chosen as a FMO fragment or monomer [168]. Structures composed of two cations and two anions (tetramers) and larger clusters of three cations and three anions (hexamers) were optimized. Single-point energy calculations were then performed for comparison with the fully *ab initio* results. Comparing the energies from FMO2 and FMO3, it could be seen immediately that the FMO method captures the total energy very well, within 2 kcal/mol in the worst case. For the tetramers, both FMO2 and FMO3 were in good agreement; the FMO2 errors were less than 1 kcal/mol relative to the fully *ab initio* results.

The molecular structure of cations and anions of EILs can be optimized by molecular design [169]. Energetic salts satisfy requirements, such as high power, high density, insensitivity, thermal stability, and environmental friendliness.

MD simulation calculations of ILs containing the Bmim cation and nitrate, azide, or DCA anions were conducted. A comparison of thermodynamic properties, such as densities, enthalpies of vaporization, and ion-binding energies as well as structural correlations obtained from simulations at atmospheric pressure and over the temperature range 298–393 K, demonstrated that ILs with the  $\text{N}(\text{CN})_2$  anion had significantly different characteristics from those of ILs with the  $\text{N}_3$  and  $\text{NO}_3$  anions [170]. This trend was further manifested in dynamical properties characterized by self-diffusion coefficients and molecular rotational relaxation times. For [Bmim][ $\text{NO}_3$ ], the simulations gave a value for  $\Delta H_{\text{vap}}$  of +145.8 kJ/mol, which was in good agreement with the experimental value (+162.4 kJ/mol). The experimental value of  $\Delta H_{\text{vap}}$  for [Bmim][ $\text{N}_3$ ] was very similar to the value of +152.5 kJ/mol predicted from simulations at 298 K. The predicted  $\Delta H_{\text{vap}}$  for [Bmim][ $\text{N}(\text{CN})_2$ ] was +195.3 kJ/mol.

## 5 Chemical Properties of ILs

Some of the very first ILs used heterocyclic cations, and tetrachloroaluminate, hexafluorophosphate, or bis(trifluoromethyl)sulfonylamidate,  $[(\text{F}_3\text{CSO}_2)_2\text{N}]^-$ , as the anions. This was useful for battery electrolytes, but not suitable for rocket propellants. Only after these salts were formulated with oxidizing anions (with some unfortunate accidents occurring in the lab), did the rocket propulsion community become aware of their potential as rocket propellants. As an example, the Emim cation was paired with many different anions and the melting points were compared to understand the effect of molecular structure on melting point [171].

## 5.1 Thermal Stability of ILs

The thermal stability of ILs is remarkable. The nature of the ILs, containing organic cations, restricts upper stability temperature limits. Pyrolysis generally occurs at 623–723 K (350–450 °C) if no other lower temperature decomposition pathways are accessible. Oxidizing anions will lower the thermal stability. In most cases, decomposition occurs with complete thermolysis and volatilization of the component fragments.

Arrhenius-type reaction rate parameters for the initiation reactions governing the thermal decomposition of several EILs, 4-amino-1,2,4-triazolium nitrate (4ATN) and HEHN, were determined by experimental and numerical techniques [172]. The supplementary, less energetic compounds studied for comparison were 4-amino-1,2,4-triazolium chloride (4ATCl) and AN. The reaction rate parameters were obtained by an algorithm that compared the difference between the experimental and simulated species evolution profiles from the decomposition process. The rates of decomposition were measured by confined rapid thermolysis (CRT). The decomposition process was then simulated by applying conservation and equilibrium equations to the condensed and gas phases individually. The processes governing the decomposition of these energetic compounds were found to be autocatalytic in nature, and the autocatalytic agents were the strong acids generated by the initial decomposition step. The activation energy ( $E_{\text{act}}$ ) and pre-exponential factor  $A$  for the unimolecular decomposition step for 4ATN, HEHN, and 4ATCl were 167–188 kJ/mol and  $1016 \text{ s}^{-1}$ , respectively, similar to previously determined values for AN.

The thermal stability data of ILs were collected in a summary publication with attention to the experimental set-up [173]. Both ramped temperature and isothermal TGA methods, along with state-of-the-art methods such as TGA-MS and pyrolysis-GC, were used to characterize the thermal stability of ILs. The strengths and weaknesses of the different methodologies known to date demonstrated that analysis methods should be in line with the application. The combination of data from advanced analysis methods would allow us to obtain in-depth information on the degradation processes. In conjunction with computational methods, the kinetics and thermodynamics of thermal degradation can be revealed step by step. The better understanding of the behavior of ILs at high temperatures allows for selective and application-driven tailored design of ILs as well as mathematical prediction of their properties.

It was attempted to predict decomposition temperatures of imidazolium-based EILs. The first simple model was based only on the number of some of atoms in cationic and anionic structures [174]. Later, a suitable correction term was added in the second correlation to adjust the predicted results for the presence of some specific cation/anion moieties. The measured data of 164 different types of imidazolium-based EILs were used to derive the new correlations. The predicted results have confirmed that insertion of a correcting function in the second correlation can provide better accuracy of the estimations. These models were also tested and compared with one of the best available group-contribution methods (where this method can be applied), for 17 additional imidazolium-based EILs containing complex molecular structures.

Rapid-scan FTIR spectroscopy and TOFMS were used to study the thermal decomposition of three imidazolium-based ILs, with Emim as the cation and  $\text{NO}_3^-$ ,  $\text{Cl}^-$ , and  $\text{Br}^-$  as the anions, at heating rates of 2000 K/s and temperatures up to 708 K (435 °C) in an ambient inert gas at 1 atm [175]. The evolution of gas-phase species indicated that the most probable sites for proton transfer and subsequent secondary reactions were primarily the methyl group, and secondarily the ethyl group. The ring appeared to remain intact, as there was no evidence of the formation of HCN, imines, or related products. The nitrate group in [Emim] $\text{NO}_3$  served as a strong oxidizer and reacted strongly with the methyl/ethyl groups at the elevated temperatures to produce combustion products.

Although the following paper deals only with ILs with non-energetic anions, the insight gained about the thermal stability of the cations is also useful for developing other (energetic) ILs. Thermal decomposition of a series of imidazolium-type IL samples was studied by pyrolysis-GC at 823 K (550 °C) [176]. As for the imidazolium halides, haloalkanes and 1-alkylimidazoles corresponding to the alkyl substituents were mainly formed through the nucleophilic attacks of halide ions to the alkyl groups followed by C–N bond cleavage, along with a small number of alkenes. Meanwhile, in the case of the ILs with  $\text{BF}_4$ ,  $\text{PF}_6$ , and  $\text{CF}_3\text{SO}_3$  anions, corresponding alkenes were predominantly produced along with 1-alkylimidazoles rather than haloalkanes. As for the samples with a longer alkyl group, the pyrolyzates reflecting the C–C bond scissions in the alkyl groups were also formed to some extent. Imidazole rings did not split under the experimental conditions at around 823 K (550 °C).

Thermal stability and thermal decomposition kinetics of  $[\text{Bmim}^+][\text{N}(\text{CN})_2^-]$  were investigated using both isothermal and non-isothermal TGA under high pure nitrogen as the carrier gas [177]. The long-term TGA studies revealed that the highest storage temperature should be 383 K = 110 °C, at which  $[\text{Bmim}^+][\text{N}(\text{CN})_2^-]$  lost less than 10% by mass in 10 h. The non-isothermal activation energy was  $147 \pm 2$  kJ/mol.

The maximum operation temperatures (MOT) of the cyano-based ILs, [Emim][DCA], [Bmim][DCA], 1-ethyl-3-methylimidazolium thiocyanate ([Emim][SCN]), [Bmim][SCN], and [Emim][TCM] have been determined using dynamic and isothermal TGA and specific heats from 296.2 to 372.2 K have been measured using DSC [178]. The MOT for [Emim][TCM] was found to be the highest, the MOT for [Emim][DCA], [Bmim][DCA], and [Bmim][SCN] was a little lower, and the [Emim][SCN] MOT was the lowest.

ILs have low vapor pressure and high heats of vaporization, so volatilization of RTILs in a flame front occurs only through thermal decomposition and vaporization of the decomposition products. A useful approach to predict decomposition mechanisms of IL systems is via quasi-classical, direct-dynamics trajectory simulations, where the motion of the molecule is followed, allowing the molecule to show the observer what the preferred reaction pathways are [72]. The direct-dynamics method dispenses with the potential energy surface. Instead, it calculates the energies, force constants, and Hessian equations on the fly using quantum chemistry methods. This method becomes computationally attractive when the dimensionality of the system increases,

particularly for RTILs, which typically contain 10 or more heavy atoms. Dynamics simulations allows the partitioning of the energy generated by exothermic reactions into vibrational, rotational, and translational degrees of freedom, thereby increasing the chance of locating new reaction pathways in the system. Several likely reaction mechanisms in the thermal decomposition of RTILs were identified by this method.

The decomposition pathways and the associated chemical kinetic parameters of energetic ionic salts based on nitrogen-rich heterocycles were studied to simulate their combustion characteristics [179]. The reaction mechanisms of four major families of energetic ionic salts, explored by various experimental and numerical techniques, were reported in detail. Droplets of [MAT][DCA] were acoustically levitated in argon and heated to successively higher temperatures by a carbon dioxide laser [110].

## 5.2 Computational Chemistry of Reactions with ILs

Whenever it becomes too difficult to examine decomposition and combustion reactions in the laboratory, computational chemistry is stepping in and trying to fill this gap of information.

MD simulations based on both electronically non-polarizable and polarizable models have been carried out to investigate the IL 1-hydroxyethyl-4-amino-1,2,4-triazolium nitrate [180]. The intent in this work was to not only provide simulation data but also to provide insight into the relationship between molecular structure, dynamics, and other useful physical properties for this class of ILs. Replacing the ethyl group in 1-ethyl-4-methyl-1,4-imidazolium nitrate by a 2-hydroxyethyl group created an IL with an interwoven network of H-bonds, which was simulated by MD calculations and the predicted glass-transition temperature closely matched that one measured by experiments.

Most borohydride-rich hypergolic ILs were very sensitive to water, but a few special examples displayed good hydrophobicity and remained very stable in air even after a month or more. The reasons behind their hydrolytic stability are unclear. Several calculation methods including ESPs, molecular orbital energy gaps, and interaction energy were used in an attempt to explain the water stability of eight typical borohydride-rich hypergolic ILs [181]. The results demonstrated that negatively charged anions with a high absolute ESP (not extrasensory perception!) values usually reacted more easily with positively charged water. The large molecular orbital energy gap with the BPB<sup>−</sup>, BCNBCN<sup>−</sup>, CTB<sup>−</sup>, and BTB<sup>−</sup> anions was related to the high degree of difficulty of interactions between anions and water, leading to a better hydrolytic stability of borohydride-rich anions. On the other hand, the relatively water-sensitive borohydride-rich anions, BH<sub>4</sub><sup>−</sup> and BH<sub>3</sub>CN<sup>−</sup>, generally had lower interaction energy with water than stable anions such as BPB<sup>−</sup> and BCNBCN<sup>−</sup>. Studies on their stepwise hydrolysis mechanism demonstrated that, in the case of all the reactions, the first step is the rate-determining step and high energy barrier values of anions correspond to good hydrophobicity.

Protonation of the anion in an IL plays a key role in the hypergolic reaction between ILs and oxidizers such as WFNA. The de-protonation energy of a set of cations has been calculated by an *ab initio* computational method to investigate the influence of the cation on the protonation reaction [182]. Specifically, guanidinium, dimethyltriazanium, triethylamine, N-ethyl-N-methyl-pyrrolidinium, N-ethyl-pyridinium, 1,4-dimethyl-1,2,4-triazolium, 1-ethyl-4-methyl-1,2,4-triazolium, and 1-butyl-4-methyl-1,2,4-triazolium were studied. The net proton transfer energy from the cations to a set of previously studied anions was calculated, demonstrating an inverse correlation between the net proton transfer energy and the likelihood that the cation/anion combination will react hypergolically with WFNA.

## 6 Combustion of ILs

### 6.1 Autoignition Temperatures of ILs

On the one hand, we want the autoignition temperature of ILs in air to be very high, in order to improve their safety and handling properties. On the other hand, these liquids may be difficult to ignite in a rocket engine when they are supposed to burn. In order to identify the initiation and secondary reactions in the condensed phase that lead to the ignition and combustion of ILs, and better understand the effects of the structure of the cation on these reactions and the amount of energy needed for ignition, two primary experimental approaches were applied: (1) laser heating coupled with tandem MS and (2) CRT coupled with FTIR and TOF MS [183]. The compounds studied using this method included: 1-ethyl-3-methyl-imidazolium nitrate, 4-amino-1,2,4-triazolium nitrate, 1-methyl, 4-amino-1,2,4-triazolium nitrate, 2-amino-4,5-dimethyl tetrazolium nitrate and 1-amino-4,5-dimethyl tetrazolium nitrate.

ILs have long been labeled and described as “not flammable” due to their low vapor pressures and measured flash points. Although so far (2013) no industrial accident involving an IL has been listed, two recently informally reported laboratory incidents during and just after synthesis of ILs containing a nitrate anion (e.g. EAN) have occurred in the EU. Both these incidents resulted in explosion events, confirming that the explosion hazard of ILs must not be neglected. More frequently, self-sustained or piloted combustion of some ILs has been shown as a potential incident scenario in some experiments. In most cases, rapid exothermic decomposition occurs when ILs with a high nitrogen content are taken to high temperatures and the subsequent decomposition products are sensitive to ignition and combustion. The ignition and combustion of non-propellant, commercially available ILs was tested by means of a fire propagation apparatus [184]. The flammability behavior of ILs is more like that of a polymer than that of a flammable liquid. The main hazard is the toxic fumes that develop during smoldering, oxygen-starved combustion.

The combustion of energetic imidazolium- or hydrazinium-based ILs may tend to be explosive even in a vacuum [185]. Burning tests performed on 4-amino-1-methyl-

1,2,4-triazolium nitrate led to a flame temperature of 2200 K [186, 187]. EILs based on 4-amino-1,2,4-triazole, with 12 different combinations of substituents (alkyl, hydroxyalkyl, methoxyalkyl, allyl, and cyanoalkyl) as cations and nitrate, dinitramide, or perchlorate as anions, were synthesized and their decomposition and combustion reactions were investigated [188].

In some cases, ILs are even combustible by design when they are intended for use as monopropellants as alternatives to hydrazine. Ultimately, once the various molecular bonds reach their thermal decomposition temperature in these carbon-based ILs, smaller and more flammable molecules could be released that lead to combustion similar to polymer combustion. These examples show that traditional flashpoint-type tests are not adequate in most cases to properly characterize the fire hazard. The flashpoint of ILs in relation to their decomposition was investigated by the estimation of vapor pressure and by the use of TGA, DSC, FTIR, and flash point analyzer apparatus [189].

This is related to a finding that ILs do not behave as traditional flammable liquids where the fire results from the combustion of the vapor phase of the concerned chemical. The flammability hazard of ILs must be revisited because they show a burning behavior more closely comparable to that of polymers rather than that of flammable solvents.

The safety of ILs relating to physicochemical hazards is very rarely investigated as it is usually perceived as a non-issue due to the lack of traditional flash points for these liquids. However, it is justified to take a detailed look at the physicochemical properties of ILs in the context of separation and purification technologies, sort out misleading from true general statements regarding their actual safety, discuss physicochemical hazard rating systems and their limitation in the context of overall risk evaluation, in addition to reporting on the early findings of a joint initiative regarding the development of predictive tools for heats of combustion of ILs and the experimental results obtained by pyrolysis combustion flow calorimetry on the effective rate of heat release from ILs in fire conditions [190].

The fundamental flammability properties of IL chemicals were determined through the use of a pyrolysis combustion flow calorimeter and a fire propagation apparatus [191]. Results so far confirmed that the combustibility potential as well as the fire behavior must be assessed on a case-by-case approach, and this is often dictated by the chemical structure of the IL. The study also illustrated how the data obtained characterize the comprehensive physicochemical hazard profiles of ILs.

## 6.2 Suspensions of Fuel Particles in ILs

4-Amino-1-methyl-1,2,4-triazolium dicyanamidate was used as an IL to suspend ball-milled nanoboron particles, creating a fuel with a very high heat of combustion suitable for air-breathing engines [192]. The IL not only suspends the particles during ball-milling, but also protects the freshly formed surface from oxidation which would

otherwise detract from the heat of combustion of the slurry [193]. A typical slurry would contain 10 mass-% boron. It can also be used as a bipropellant fuel with NTO or RFNA as the oxidizer.

The structure of two different EILs and the nature of their binding to elemental boron surfaces were investigated by a combination of X-ray photoelectron and IR spectroscopy, zeta potential measurements, TGA, and calculations based on first-principles theory [194]. It was found that both [MAT][DCA] and [Bmim][DCA] ILs bind to boron well enough to resist removal by ultrasonic washing and protect the boron surface from oxidation during exposure of the washed powder to the air. The data suggested that both the cation and the anion of the ILs interact with the boron surface.

## 7 Safety Properties of ILs

ILs have been advertised as the ultimate safe rocket propellants and battery electrolytes, due to their low or non-existent vapor pressure and flammability. However, some investigators have overlooked the fact that many ILs (including those that are commercially available) are potentially explosive due to the presence of oxidizing ions and the positive enthalpy of formation of the heterocyclic ring compounds [47, 185].

### 7.1 Flammability of ILs

RTILs have been identified as non-volatile, non-flammable compounds with a wide range of applications. However, numerous thermal studies have identified volatile decomposition products and a source for fuel, raising questions regarding the fire hazard of ILs. The flammability properties of imidazolium-based ILs have been measured using cone calorimetry and microscale combustion calorimetry [195]. The combustion data were compared to flashpoints estimated from the TGA data. The resulting flammability properties of ILs were comparable to aliphatic hydrocarbon plastics (polyethylene and polyamide) and were lower than those of high-boiling organic solvents.

### 7.2 Explosive Properties of ILs

Besides the ILs that are being developed as replacements for 1,3,5-trinitro-1,3,5-triazine (RDX) and 2,4,6-trinitrotoluene (TNT) and are intended as explosives, some EILs may constitute an unexpected explosive hazard in the laboratory. A batch of the pIL pyrrolidinium nitrate exploded while drying it under reduced pressure at 383 K (110 °C) using a rotary evaporator with an oil bath [47].

## 8 Toxicity of ILs

Many ILs are intended to replace more toxic propellants. They have been described as “green” (i.e. environmentally friendly) propellants. Before ILs are allowed to be widely used with relaxed safety precautions regarding personnel-protective equipment, it would be wise to make sure that there are no hidden, yet unrecognized and unanticipated risks in producing, handling, and disposing of these compounds. Appendix F of a report on environmentally sustainable liquid gas generator formulations [196] contains a summary of the toxicity of candidate propellant ingredients, also published as a separate report [197].

## 9 Environmental Impact of ILs

Byproducts of the synthesis of ILs need to be disposed of in a safe manner, and this may complicate the overall equation of environmental benefits of switching to ILs. For comparison, the only byproduct in the synthesis of hydrazine hydrate by the Raschig method is sodium chloride brine which is easy to dispose of. The synthesis of heterocyclic amines produces a wide array of byproducts which must be disposed of as hazardous materials.

A systematic investigation of the biodegradability of pyrrolidinium-, morpholinium-, piperidinium-, imidazolium-, and pyridinium-based IL cations substituted with different alkyl or functionalized side chains was performed by specific analysis and/or their ultimate biodegradability using biochemical oxygen-demand tests according to the Organisation for Economic Co-operation and Development (OECD) guideline 301F [198]. Biological transformation products were investigated using MS. A comparison of the biodegradation potential of these ILs showed that, for all five compound groups, representatives can be found that are readily or inherently biodegradable, thus permitting the structural design of ILs with a reduced environmental hazard. If spilled in surface waters, most heterocyclic ILs are actually more persistent than hydrazine because they autoxidize more slowly.

The life-cycle environmental impacts of ionic salts and liquids like high-energy materials, propellants, and explosives have not been sufficiently studied. Environmental impacts arise both from the release of these energetic materials themselves as well as from the byproducts of their synthesis. ILs require multi-step synthesis operations and none of the steps operates at 100% yield, leaving byproducts and contaminants along the way which need to be disposed of. A cradle-to-grave life-cycle environmental impact study looked at the production of the energetic ionic salt 1,2,3-triazolium nitrate and compared it to a traditional energetic material, TNT [199]. The results indicated that the production processes of ionic salts may have a significantly higher environmental footprint than conventional energetic materials. The conclusion was the same across all nine impact categories analyzed and can be directly attributed to

the energy-intensive steps needed to prepare ionic salts (liquids) and their precursors. The findings suggested that ionic energetic materials may have a higher environmental impact than TNT from a complete life-cycle perspective.

Motivated by the prevailing need for a sustainable development and taking the principles of *Green Chemistry* as a starting point, conditions regarding a sustainable product design for ILs were reviewed with a focus on environmental risk [200]. Cytotoxicity testing and first indicative results from a genotoxicity study extend the present knowledge, also with regard to the possible effects on humans. The structural variability of commercially available ILs leads to consequences for an integrated risk assessment accompanying the development process of ILs. The side-chain effect on toxicity for imidazolium-type ILs required more complex biological testing. Also, the influence of anions on cytotoxicity was examined for the first time. Testing of presumed metabolites of the imidazolium-type cations showed a significantly lower biological activity in cytotoxicity studies than their parent compounds. In addition to the risk analysis, a life-cycle analysis for the multi-objective problem of designing ILs was described and an eco-friendly design scheme for ILs was proposed.

ILs were initially proposed as replacements for conventional organic solvents. However, their chemistry and range of applications has expanded remarkably and offers unexpected opportunities in numerous fields, ranging from electrochemistry to biology and rocket propulsion. As a consequence of ILs advancing towards potential and actual applications, a comprehensive determination of their environmental, health, and safety impacts is now required. A critical review aimed to present an overview of the current understanding of the toxicity and environmental impact of the principal IL groups, and it highlighted some emerging concerns [201]. Each cation type was considered separately, examining the significance of the biological data, and identifying the most critical questions, some yet unresolved. The need for more studies, and greater detail, was emphasized.

## 10 ILs as Rocket Propellants

ILs are an exciting class of compounds with unique properties that make them attractive for many industrial applications. Among their valuable features, an immeasurably low vapor pressure and a liquid state at or near-ambient room temperature conditions are of interest to the rocket propellant chemist. For a rocket propellant chemist, EILs can be divided into two categories: potential bipropellant fuels (hypergolic systems) and monopropellants (self-oxidizing systems). The first category encompasses a wide range of cations, from N-rich ammonium and hydrazinium, to tetrazolium and other cationic *N*-heteroaromatic rings as well as various anions, such as nitro- and cyano-containing or borohydride-based anions. The energetic behavior of such bipropellant fuels requires a reaction with a liquid oxidizer. The second category consists of an ionic pair made up of a combustible N-rich cation with an oxidizing acid anion, which

make these EILs stoichiometrically oxygen-balanced (or nearly oxygen-balanced) and prone to self-oxidation.

The research on EILs typically involves aliphatic or heterocyclic amines as the cation. For aliphatic amines, the cation may be formed from 1,2-bis(oxyamine)-ethane, 1,2-bis(oxyamine)propane, or dimethyl(azidoethyl)amine. For heterocyclic amines, imidazolium, triazolium, or tetrazolium cations are combined with DCA, tetrazolate, or other anions to make fuels and oxidizing acids (nitrate, perchlorate, trinitromethide, and dinitramide) for monopropellants and explosives [202]. Many are salts which are liquids at room temperature and are being evaluated as monopropellants by themselves (if they have nitrate or perchlorate ions), as fuels for HAN- or hydroxylammonium perchlorate (HAP)-based monopropellants, as replacements for monomethylhydrazine (MMH) as a hypergolic fuel in bipropellant combinations, and as working fluids for colloid thrusters [81, 171, 203–206]. EILs with a high nitrogen content offer several potential advantages over traditional monopropellants such as hydrazine and storable fuels such as methylhydrazine. These are the types of ILs and propellants discussed here. A logical approach to achieve targeted combinations of physical and chemical properties by tuning the selection of the cation and anion independently is described in [207]. This publication, with 80 references, contains sections on triazolium-based ionic salts, tetrazole-based, urotropinium-based, tetrazine-based, azetidinium-based, picrate-based, and imidazolium-based salts as well as polynitrogen compound-containing salts. However, most of these have melting points above 373 K (100 °C) and are not in the category of ILs. Another good survey paper is [208]. Both publications offer very good summaries of energetic ionic solids and liquids including work done through 2006.

Other publications, mostly collections of presentation charts, are useful introductions to the study of ILs as rocket propellants, describing early advances of this technology, providing updates on the current status of the research, and outlining targets for future exploration [209–212]. A summary review with 26 references of IL rocket propellant work done by the Shreeve group in Idaho and others was published in 2013 and is a good survey and status report as of that year [213].

An excellent summary in the field of EILs with 98 references was published in 2014 [3]. This is a good introduction and explains that the intrinsic properties of ILs, e.g. low vapor pressures, high thermal stabilities, and low melting points, make them ideal candidates for minimizing or even eliminating the hazardous conditions associated with handling, processing, and transporting conventional storable rocket propellants. In order to achieve low melting points, ILs make use of bulky, asymmetric, poorly packing ions to lower their lattice energy. Favorite choices are quaternary ammonium and *N*-heteroaromatic cations. The *N*-heteroaromatic ions have been found to be energetic when combined with appropriate counter-ions. This arises from the numerous energetic N–N and C–N bonds which lead to high heats of formation.

IL rocket propellant development projects are in progress in many countries in the world, including Germany, France [214], Russia, Japan, and China [215].

## 11 ILs as Monopropellants

Historically, most anions paired with IL cations were either non-oxidizing ( $\text{BF}_4^-$  and  $\text{PF}_6^-$ ) or moderately oxidizing ( $\text{NO}_3^-$  and  $\text{ClO}_4^-$ ) anions carrying insufficient oxygen to achieve complete combustion of the organic skeleton and appending alkyl groups. Searching for anions that carry sufficient oxygen to achieve complete combustion to carbon monoxide, carbon dioxide, nitrogen, and water has led to the identifications of polynitrato or polyperchlorato complex anions with very high oxygen contents.

While most ILs are underoxidized with a negative oxygen balance, making them more useful as fuels in bipropellants than as monopropellants in their own right, combining a heterocyclic cation with an oxygen-rich anion like tetranitratoaluminate can create oxygen-balanced ILs and potential IL monopropellants where one does not have to mix water-soluble oxidizers and fuels. One of the first oxygen-balanced ILs in this category was 1-ethyl-4,5-dimethyltetrazolium tetranitratoaluminate [86, 87]. In this IL molecule, the tetranitratoaluminate anion contains 12 oxygen atoms; of these, 10.5 are available to oxidize a fuel cation. A 1-ethyl-4,5-dimethyltetrazolium cation was chosen because of its positive enthalpy of formation and ability to form an RTIL with the tetranitratoaluminate anion. The resulting energetic salt is a colorless liquid at room temperature. Its spontaneous ignition temperature is 473 K (200 °C).

One of the EILs is described in a patent [216]. One of the examples listed in this patent is Emim tetranitratoborate,  $[\text{C}_6\text{H}_{11}\text{N}_2][\text{B}(\text{ONO}_2)_4]$ , which can be prepared in a one-step process through the reaction of Emim chloride, boron trichloride, and excess dinitrogen tetroxide.

The products of the reaction are easily separated, because nitrosyl chloride is highly volatile and easily removed from the desired reaction product, which, as an IL, has essentially no vapor pressure. Other oxygen-rich anions proposed for such propellants are  $\text{P}(\text{ONO}_2)_6^-$ ,  $\text{B}(\text{OCIO}_3)_4^-$ ,  $\text{Al}(\text{OCIO}_3)_4^-$ , and  $\text{Ti}(\text{ONO}_2)_5^-$ .

HEHN is an IL that does not readily crystallize at room temperature. Solutions of HEHN can be decomposed on Shell 405 catalysts [217, 218]. The 2-HEH dinitrate reacts with Shell 405 catalysts in a similar fashion. HEHN has also been considered and tested as a bipropellant fuel in combination with RFNA, NTO, or 98% HTP [219].

It is difficult to see anything novel in a 2014 patent claiming an EIL catalytic decomposition gas generator using stoichiometric and non-stoichiometric mixtures of EILs and iridium catalysts [220]. One of the monopropellants claimed is a mixture of 2-HEHN and 2-HEH dinitrate. Virtually all aspects of this patent have been described in the open literature, in particular 2-HEHN has been patented as a fuel in monopropellants with iridium catalysts and is described in previous articles [221].

A dual-mode spacecraft might use monopropellants for high-thrust maneuvers and electrical propulsion for low-thrust, long burn-time maneuvers. Imidazole-based

ILs were investigated in terms of dual-mode chemical monopropellant and electro-spray rocket propulsion capabilities [222]. The ILs [C4mim][DCA], C4mim nitrate, and Emim ethylsulfate meet or exceed the storability properties of hydrazine, and their electrochemical properties indicate that they may be capable of electro-spray emission in the purely ionic regime. These liquids were projected to have a 13–23% reduced monopropellant propulsion performance in comparison to hydrazine due to the prediction of solid carbon formation in the exhaust. The use of these ILs as a fuel component in a binary monopropellant mixture with HAN would deliver a 1–4% improved  $I_{sp}$  over some other “green” monopropellants. Also, this avoids volatility issues and reduces the number of electro-spray emitters by 18–27% and the power required by 9–16%, with oxidizing IL fuels providing the greatest savings. A fully oxygen-balanced IL will exceed the state-of-the-art performance in both modes but will require advances in hardware technology in both modes to achieve minimum functionality and meet mission-life requirements.

The high combustion temperature of IL monopropellants make the use of typical ignition catalyst beds prohibitive, since conventional catalysts cannot withstand the elevated temperatures. Laboratory studies were conducted using alternative ignition techniques such as laser-induced-spark ignition and hot-wire ignition [223]. Ignition delay, defined as the time between the introduction of the ignition source and the first sign of light emission from a developing flame kernel, can be measured using Schlieren visualization. An optically accessible, liquid monopropellant burner was planned to be used to determine propellant burn rates as a function of pressure and initial propellant temperature via high-speed imaging through the chamber’s windows.

In an effort to find less-toxic monopropellants as replacements for hydrazine and less sensitive and with lower combustion chamber temperatures than AF-M315E, material candidates based on ILs were evaluated as possible hydrazine replacements [196]. The target combustion chamber temperature was <1450 K. The target viscosity was <1000 cPs. The program evaluated cations from the triazole, tetrazole, pyrimidinium, hydrazide, and imidazole family, and the perchlorate, dinitramide, and nitrate anions. Initial evaluations examined the performance, sensitivity, catalytic response, thermal stability, and toxicity of each candidate. Overall, the triazoles and hydrazides exhibited acceptable properties. Both candidate families exhibited good ignition, enthalpy of formation, and reactivity. The imidazoles were the first to be eliminated from further evaluations due to poor performance. The tetrazoles were eliminated due to insufficient thermal stability and the pyrimidium salts due to poor catalytic ignition. Nitrates were determined as the only acceptable cation. Perchlorates were eliminated due to environmental concerns (HCl in the exhaust) while dinitramides exhibited an unacceptably low onset of exotherm temperatures. The 1-methyl-4-amino-1,2,4-triazolium nitrate candidate was selected because of its good performance. A carbohydrazinium nitrate formulation was selected because of

its high performance and the commercial availability and low cost of carbohydrazide. A diluted AF-M315 formulation was included due to its high maturity level and ability to meet the targeted flame temperature requirement. Candidate fuel ingredients were selected from a list of 51 chemicals, many of these being ILs. Theoretical rocket performance and combustion chamber temperatures were calculated for HAN/H<sub>2</sub>O in combination with 36 of these fuels. HEHN was included as a baseline. A new propellant formulation contained HAN and 1-(2-hydroxyethyl)-4-amino-1,2,4-triazolium nitrate. Rocket engine test results with four of these new monopropellants will be discussed in *Encyclopedia of Monopropellants*.

Multi-mode space propulsion systems are being proposed that combine high- $I_{sp}$  electric propulsion and high-thrust chemical propulsion. The most important attribute of this concept is a shared propellant feed system capable of both modes of propulsion, which adds to mission flexibility. One promising approach is a catalytic monopropellant thruster paired with an electrospray electric thruster. Previous research has identified an IL consisting of 41 mass-% Emim ethyl sulfate and 59% HAN as a promising propellant candidate. The burn rate of this monopropellant was measured through pressure-based and high-speed imaging methods in a fixed-volume chamber at pressures from 0.5 to 10 MPa [224, 225]. The burn rate of the multi-mode monopropellant was found to follow an exponential law given by

$$r_b = 5.35P^{1.11}$$

between 0.5 and 3 MPa, and it was approximately constant at  $142 \pm 29$  mm/s between 3 and 10 MPa.

During the discussion of HAN-based monopropellants with ionized fuels (fuel salts), we already pointed out that these solutions have unique properties which place them in the category of ILs, in particular if they are formulated without any water. HAN and many nitrate salts form low-melting eutectics which can be described as ILs.

Otherwise, the research on EILs typically involves triazolium or imidazolium salts which are liquids at room temperature and are being evaluated as monopropellants by themselves (if they have nitrate, dinitramide, or perchlorate ions), as fuels for HAN- or HAP-based monopropellants, and as working fluids for colloid thrusters. EILs with a high nitrogen content offer several potential advantages over traditional monopropellants like hydrazine. These are the types of propellants (all those not using HAN) discussed here. ILs as monopropellants can be decomposed on platinum group-supported catalysts similar to those used for hydrazine or ADN- or HAN-based monopropellants [226].

## 12 ILs as Hypergolic Fuels

Initially, much of the work on EILs was on heterocyclic cations in combination with oxygenated anions such as nitrate or perchlorate, which frequently had stability and safety problems. ILs can also be used as low-volatility, low-toxicity fuels in hypergolic or non-hypergolic bipropellant combinations.

In a bipropellant system with ILs used as fuels, it is not necessary to use an oxygen-balanced IL. One can avoid oxygen-carrying anions completely, which, other things being equal, should make handling much safer because the fuel and the oxidizer are chemically and physically separated. In an ionic salt system, the positive charge of the cation makes it more resistant toward oxidation. Consequently, electron- and fuel-rich anions are much easier to oxidize and thus would seem to hold the potential to promote hypergolic ignition.

Because the ILs are very viscous, it is difficult to achieve complete mixing of IL hypergolic fuels with the oxidizers, for instance WFNA, NTO, or HTP. Even more difficult would be to achieve mixing between an IL fuel and an IL oxidizer and get them to ignite hypergolically without a significant ignition delay and ignition pressure spike. The first attempts to achieve hypergolic ignition with WFNA or RFNA and ILs were not very encouraging, but led the way to substantial improvements in shortening the ignition delay [227].

The basic molecule design strategy to make hypergolic ILs is to incorporate reactivity in the cation and/or anion through the incorporation of chemical bonds known to induce a hypergolic reaction with common oxidizers, such as the  $\text{N}-\text{C}\equiv\text{N}$  bond, e.g. in  $[\text{DCA}]^-$ , or  $\text{B}-\text{H}$  bonds, e.g. the  $[\text{B}(\text{CN})_2\text{H}_2]^-$  anion or the boronium cation [228]. Even with this designed reactivity, many other physical and chemical properties, such as viscosity or density, play a large role in the mixing, ignition, and combustion processes that occur upon contact. It is hard to predict which cations should be paired with already-known hypergolic anions and whether the modified physical properties or the introduced functional groups can take the credit for any enhanced reactivity.

One of the few hypergolic ILs derived from an aliphatic amine instead of a heterocyclic amine is 2-azidoethyltrimethylammonium nitrocyanamidate [229]. Its ignition delay with WFNA was of the order of 8 ms, equal to that of MMH. Another IL, bis(2-azidoethyl)dimethylammonium DCA, also gave a useful IL hypergolic fuel with an ignition delay of 20 ms. One azido group can add approximately 280 kJ/mol to the heat of formation of a molecule. In contrast, in the absence of azide functional groups, some imidazolium ILs, based on the nitrocyanamidate anion only, displayed relatively longer ignition delay times (e.g. 78 ms for 1-methyl-3-ethylimidazolium nitrocyanamidate **(I)** and 46 ms for 1-methyl-3-acrylimidazolium nitrocyanamidate **(II)**) [112].

Although both hypergolic ILs (**I** and **II**) are liquids at room temperature and also exhibited relatively low viscosities (23 and 44 cPs at 298 K = 25 °C, respectively), their long ignition delay time (>45 ms) significantly decreased their practical application potentials as hypergolic fuels.

ILs previously proposed as hypergolic fuels for the replacement of hydrazine, MMH, or UDMH must have low volatility and favorable fluid transport properties. While many IL-forming anions {e.g., azide  $[\text{N}_3]^-$ , dicyanamidate  $[\text{N}(\text{CN})_2]^-$ , nitrocyanamidate  $[\text{N}(\text{CN})(\text{NO}_2)]^-$ , and dicyanoborohydride  $[\text{B}(\text{CN})_2\text{H}_2]^-$ } have been shown to be hypergolic with nitric acid or hydrogen peroxide, many other practical properties must also be considered in the design of hydrazine replacements.

*N,N*-Dimethylhydrazinium DCA and nitrocyanamide ILs were prepared by quaternization of UDMH with alkyl halides, followed by metathesis reactions with silver DCA or silver nitrocyanamide, and then evaluated as hypergolic fuels [230]. The key physicochemical properties, such as melting point and decomposition temperatures, density, viscosity, heat of formation, detonation pressure and velocity, and  $I_{\text{sp}}$  were measured or calculated. Spot plate droplet tests with WFNA as an oxidizer showed that the 14 new *N,N*-dimethylhydrazinium salts are hypergolic, with ignition delay times ranging from 22 to 1642 ms, suggesting that some may have potential as non-volatile bipropellant fuels.

Fourteen different ionic salts were prepared with tetramethylguanidinium, alkyl- and amino-1,8-diazabicyclo[5.4.0]undec-7-ene (DBU) and alkyl-1,5-diazabicyclo[4.3.0]non-5-ene (DBN) as the cations, and DCA and cyanoborate as anions, characterized by  $^1\text{H}$ - and  $^{13}\text{C}$ -NMR and IR spectroscopy, and HR-MS, and evaluated as hypergolic fuels [231]. Their physicochemical properties such as thermal properties, density, viscosity, heats of formation,  $I_{\text{sp}}$ , and ignition delay time were characterized or calculated. Among the 14 new organic ionic materials, 11 salts were liquids at room temperature, and all exhibited good thermal stability. The densities of these ionic compounds ranged from 1.00 to 1.22 g/cm<sup>3</sup>, and their enthalpies of formation varied between -38.0 and +478.6 kJ/mol. Surprisingly, most of these new ILs exhibited an unexpected high thermal stability of >280 °C. These novel IL materials had extremely low vapor pressures, short ignition delay times upon contact with WFNA, and high thermal stability. See also [232–235].

Chemists worldwide have been motivated to develop alternative, environmentally friendly hypergolic IL propellants as fuels. Anions of these salts, which include DCA, dicyanoborate, cyanoborate, azide, nitrate, aluminum borohydride, nitrocyanamide, etc., appear to play the major role in determining hypergolic ignition properties. Although cations play a lesser role, they are most frequently nitrogen-containing

alkyl and heterocyclic species, e.g. substituted alkyl ammonium, imidazolium, imidazolium-substituted compounds with alkyl, vinyl, or propargyl groups [236].

A report on methods for predicting hypergolic-mixture flammability limits contains a good historical summary of ILs as hypergolic fuels their thermodynamic properties and flammabilities, and predicted flame temperatures when in contact with various oxidizers [237].

The previous section discussed ILs as hypergolic fuels for bipropellant combinations without narrowing the discussion down to a specific group of cations or anions. The following sections deal with ILs as hypergolic fuels where the cation and/or the anion are identified. The ultimate goal would be to not only replace toxic fuels with less toxic IL hypergolic fuels, but to replace both conventional hypergolic fuels and oxidizers with ILs that have very low vapor pressures [238].

## 12.1 ILs as Hypergolic Fuels, Sorted by Cations

The structures of heterocyclic ring amines with various substituents attached to the ring determine the ignition delays of various ionic liquids with oxidizers like WFNA, RFNA, or HTP. Substituents with unsaturated alkyl groups attached to a ring structure like imidazole make good hypergolic fuels [228, 239].

### 12.1.1 IL Hypergolic Fuels Derived from Ethylenediamine

Four energetic salts (including two ILs), based on 2-(dimethylamino)-*N,N,N*-trimethylethanaminium and *N,N'*-dialkyl-*N,N,N',N'*-tetramethylethane-1,2-diaminium, were prepared and characterized by  $^1\text{H}$ - and  $^{13}\text{C}$ -NMR, IR, and Raman spectroscopy, and elemental analysis, melting and decomposition temperatures, density, viscosity, enthalpy of formation, detonation performance, and  $I_{\text{sp}}$  [25]. With thermal stability up to 473 K (200 °C), the resulting ILs showed densities from 1.02 to 1.19 g/cm<sup>3</sup> and heats of formation from +85.1 to +154.4 kJ/mol. The IL-2-(dimethylamino)-*N,N,N*-trimethylethanaminium DCA is hypergolic with WFNA and exhibited good potential as a green fuel for bipropellant combinations.

### 12.1.2 IL Hypergolic Fuels Derived from Imidazole

Alkylimidazolium bromides are useful precursors for the synthesis of EILs by metathetical reactions with silver nitrate, DCA, nitrocyanamide, or perchlorate [240].

The hypergolic reactions of 1[Amim][DCA], [Emim][DCA], and [Bmim][DCA] with nitric acid were investigated [241]. [Amim][DCA] was characterized by DSC, TGA, and density. Rheological measurements were performed on pure and gelled [Amim][DCA] with silicon dioxide nanoparticles. The enthalpy of formation was calculated from the heat of combustion and the performance with nitric acid was calculated. The calculated results for ILs were compared to MMH and UDMH, which they are intended to replace. The mass-specific impulse of [Amim][DCA] is lower than that of MMH and

UDMH. However, the volume-specific impulse of [Amim][DCA] is higher than that of the traditional hypergolic fuels.

DCA-based ILs containing mono- and dicationic counterparts were synthesized and characterized [242]. The physical properties of these salts, including thermal stability, melting point, density, and viscosity, are highly dependent on the structure of the cation and the type of anion. Spot plate droplet tests were used to investigate the hypergolic properties of these ILs. All of the synthesized compounds showed hypergolic activity upon contact with WFNA.

A QSPR modeling method was developed for predicting the ignition delay time of 31 hypergolic imidazolium IL derivatives with WFNA as the oxidizer [243]. Chemical structures of these ILs were encoded into several sets of molecular descriptors, representing various physical and chemical properties of these molecules. A total of 1447 molecular descriptors with different types (e.g. constitutional, functional group counts, and geometrical descriptors) were selected and calculated. A combination of stepwise and best-subset regression approaches was used to determine the molecular descriptors which have the strongest influences on the ignition delay time of hypergolic imidazolium IL derivatives. The derived model displayed a good predictive ability, arising from the determination coefficient corresponding to the leave-one-out cross-validation technique. The predictive power of the proposed method was evaluated using several different techniques and this method can be used as a reliable tool for designing improved hypergolic ILs.

A new set of synthesized ILs combined the advantages of conventional rocket propellants with the energy characteristics of acetylene derivatives [244]. N-alkylated imidazoles (alkyl = ethyl, butyl) have been synthesized and alkylated with propargyl bromide followed by metathesis using silver DCA. Modified hypergolic drop tests of N-ethyl (IL-1) and N-butyl propargylimidazolium (IL-2) ILs with WFNA were performed using high-speed shadowgraph imaging to visualize the ignition process. The temperature rise due to ignition was monitored with a 2-color photodetector. It was shown that the ignition delay was shorter for IL-1 than for IL-2. The ignition of IL-1 occurred in two stages, whereas the combustion of IL-2 proceeded smoothly without secondary flashes.

The anions  $\text{DCA}^-$ ,  $\text{CBH}^-$  and cations  $\text{Emim}^+$  and  $\text{Amim}^+$  were mixed in different ratios to form hypergolic ionic mixtures and their viscosity, density, decomposition temperature, and  $I_{\text{sp}}$  were determined and calculated [245]. Ignition delay times were measured by a spot plate drop test recorded by a high-speed camera. The results indicated that ionic nature and ionic ratio were two decisive factors for the properties of ionic mixtures. Specifically, mixture [Emim][CBH]0.7[DCA]0.3 possessed the shortest ignition delay time of 3 ms with WFNA as the oxidizer, which was shorter than that of pure IL [Emim][DCA] (32 ms) or [Emim][CBH] (8 ms) alone. However, with a reverse ratio of anions, the mixture [Emim][CBH]0.3[DCA]0.7 possessed a very long ignition delay time of 373 ms and showed a different phenomenon in the ignition process. TGA indicated that mixture [Emim][CBH]0.7[DCA]0.3 decomposed faster than mixture [Emim][CBH]0.3[DCA]0.7. As a new design strategy, hypergolic IL mixtures

can not only combine properties of different ions, but can also show a more favorable performance in a specific ionic ratio than each parent IL by itself.

Three hypergolic ILs, from the cation Amim combined with the DCA, CBH, or SCN anions, were prepared and evaluated as hypergolic fuels [228]. Their viscosity, density, melting point, energy properties, and  $I_{sp}$  were measured and calculated. A hypergolicity evaluation scheme was established to predict the hypergolicity and guide the design of new hypergolic ILs. See also [246].

### 12.1.3 IL Hypergolic Fuels Derived from Triazole

Bipropellant ILs that react hypergolically with WFNA were tested to gain a fundamental understanding of the ignition of EILs with WFNA [247]. The effects of cation and anion structure on initiation reactions, and the subsequent reactions leading to ignition for representative compounds in three classes of compounds (amino-1,2,4 triazoles, amino-1,2,3-triazoles, and amino-tetrazoles) were investigated. Thermal decomposition of the EILs, 1-methyl-4-amino-1,2,4-triazolium nitrate and 1-amino-3-methyl-1,2,3-triazolium nitrate, was studied by CRT. In the FTIR spectrum of species from CRT of 1-methyl-4-amino-1,2,4-triazolium nitrate at 593 K (320 °C) and 1 atm, nitric acid with several rovibrational bands from 1700 to 800  $\text{cm}^{-1}$  and an overtone above 3500  $\text{cm}^{-1}$ , was immediately discernable as a major species. The other major species detected were  $\text{H}_2\text{O}$ ,  $\text{N}_2\text{O}$ , and  $\text{CO}_2$ . Also identified were small quantities of isocyanic acid (HNCO) and HCN. In order to explain the effects of substituents, the decomposition products and their temporal evolution over a range of temperatures were analyzed.

### 12.1.4 IL Hypergolic Fuels Derived from Tetrazole

A series of hypergolic (2-methyltetrazol-5-yl)diazotates have been synthesized by treatment of ammonia, hydrazine, guanidine, aminoguanidine, diaminoguanidine, and triaminoguanidine with (2-methyltetrazol-5-yl)diazotatic acid [248]. The melting points of these salts were between 98 and 194 °C, so they are not ILs. These energetic salts showed remarkably short ignition delay times by droplet test with WFNA. All compounds were fully characterized using IR,  $^1\text{H}$ - and  $^{13}\text{C}$ -NMR spectroscopy, DSC and, in the case of aminoguanidinium (2-methyltetrazol-5-yl)diazotate and diaminoguanidinium (2-methyltetrazol-5-yl)diazotate, single-crystal XRD.

### 12.1.5 IL Hypergolic Fuels with Boron-Containing Cations

Two series of boronium-cation-based ILs were prepared and characterized by  $^1\text{H}$ -,  $^{13}\text{C}$ -, and  $^{11}\text{B}$ -NMR and IR spectroscopy, DSC, and elemental analysis [249]. The structure of bis(1-methyl-1*H*-imidazole-3-yl)dihydroboroniumdicyanoborohydride (5a) was determined by single-crystal XRD. The densities of these ILs ranged from 1.05 to 1.28  $\text{g}/\text{cm}^3$ , and the enthalpies of formation, predicted on the basis of Gaussian 03 calculations, were between -164.6 and +430.5 kJ/mol. Bis(1-allyl-1*H*-imidazole-3-

yl)dihydroboroniumdicyanoborohydride exhibited the lowest viscosity (35 mPa s) and shortest ignition delay time (14 ms) when in combination with WFNA.

Hypergolic ILs based on the [imidazolyl–amine–BH<sub>2</sub>]<sup>+</sup> cation combined with fuel-rich anions, such as the N(CN)<sub>2</sub><sup>−</sup> and BH<sub>3</sub>CN<sup>−</sup> anions, were synthesized and characterized. As expected, all of the ILs exhibited spontaneous combustion upon contact with WFNA. The densities of these ILs varied from 0.99 to 1.12 g/cm<sup>3</sup>, and the enthalpies of formation, predicted based on Gaussian 09 calculations, were between −707.7 and +241.8 kJ/mol. 1-Allyl-1*H*-imidazole-3-yl-(trimethylamine)-dihydroboronium DCA exhibited the lowest viscosity (168 MPa s), good thermal properties ( $T_g < 203\text{ K} = < -70\text{ }^\circ\text{C}$ ,  $T_{dec} > 403\text{ K} = > 130\text{ }^\circ\text{C}$ ), and the shortest ignition delay time (18 ms) with WFNA [250–252].

Boronium cation-based ILs exhibited relatively low viscosities and short ignition delay times in combination with WFNA [249]. Two series of boronium cation-based ILs were prepared and fully characterized by <sup>1</sup>H-, <sup>13</sup>C- and <sup>11</sup>B-NMR and IR spectroscopy, DSC, and elemental analysis. The structure of bis(1-methyl-1*H*-imidazole-3-yl)dihydroboronium dicyanoborohydride was determined by single-crystal XRD. The densities of these ILs ranged from 1.05 to 1.28 g/cm<sup>3</sup>, and the heats of formation, predicted on the basis of Gaussian 03 calculations, were predicted to be between −164.6 and +430.5 kJ/mol. Bis(1-allyl-1*H*-imidazole-3-yl)dihydroboronium dicyanoborohydride exhibited the lowest viscosity (35 mPa s) and shortest ignition delay time (14 ms) in combination with 100% HNO<sub>3</sub>. It had a melting point of less than 193 K (−80 °C), a low viscosity of 35 MPa s at 298 K (25 °C), and its ignition delay time was 14 ms when WFNA was used as the oxidizer. In this hypergolic salt, both the boronium cation and the dicyanoborate anion contain two B–H bonds, which is probably an important contributor to the hypergolicity of this IL. See also [253].

Phosphorus is common in pyrotechnic igniters, but is not a preferred element to have in rocket propellants. ILs with bis(borano)hypophosphite anions [254] or boranophosphate ions [255] are hypergolic with WFNA or HTP.

## 12.2 ILs as Hypergolic Fuels, Sorted by Anions

The hypergolic activity of ILs with NTO, RFNA, or WFNA, or even HTP is usually determined by the type of the more mobile anion than by the asymmetric cation. The following section provides a listing of candidate hypergolic fuels arranged by the common anion.

### 12.2.1 ILs with DCA Anions as Hypergolic Fuels

[Bmim][DCA], CAS RN [44824-52-1], is a potential hypergolic fuel for bipropellant engines [99, 151]. Its density at 297 K (24 °C) is 1.0580 g/cm<sup>3</sup> and at 355.8 K (82.7 °C) it is 1.0258 g/cm<sup>3</sup>. It has a glass-transition temperature of 183 K (−90 °C) and a melting point of 267 K (−6 °C).

The patent literature describes numerous hypergolic bipropellants formed by combining an IL fuel having a DCA anion and a nitrogen-containing heterocyclic cation, with a liquid oxidizer, more specifically, an IL fuel that contains at least one DCA anion and a nitrogen-containing heterocyclic-based cation selected from the group comprising imidazolium, triazolium, pyrrolidinium, pyridinium, and tetrazolium [256].

The Air Force Research Laboratory (AFRL) conducted a program to develop the capacity to experimentally determine and theoretically validate hypergolic ignition mechanisms in ILs, to provide a roster of hypergolicity of hydrazine, MMH, and triazolium IL–oxidizer pairs, to provide ignition mechanisms for a reference set of IL–oxidizer reactions with time-resolved spectroscopic techniques, theoretically validate predictions for experimental results, and develop a predictive model to suggest targets for future development and screening for IL synthesis candidates [209, 257].

In order to more accurately measure ignition delays with IL fuels in comparison to other hypergolic fuels, the AFRL developed an ignition delay tester using a line-of-sight electro-optical circuitry with a direct digital readout and an additional oscilloscope recording that can be used to measure total ignition and chemical delay times for screening candidate fuels [258]. A falling drop interrupts a light beam and starts a counter. A photodiode detects the first flash of light and stops the counter. The use of a 1-MHz time base gives the chemical delay directly in microseconds upon subtraction of counter 1 from counter 2. The ignition delay of WFNA/MMH measured for comparison was 14.7 ms, but ignition delays of WFNA with IL fuels were substantially longer. The properties of six imidazolium DCA salts with different alkyl group substituents are summarized in Table 3.

**Table 3:** Properties of 3-methylimidazolium DCA salts with different alkyl group substituents

| 1-R-3-methylimidazolium           | Glass temperature |     | Melting point |     | Decomposition onset |      | Viscosity at 298 K (25 °C) | Ignition delay, ms |      |
|-----------------------------------|-------------------|-----|---------------|-----|---------------------|------|----------------------------|--------------------|------|
|                                   | K                 | °C  | K             | °C  | K                   | °C   |                            | IRFNA              | WFNA |
| 1-allyl-                          | 188               | –85 | —             | —   | 480                 | +207 | 42                         | 625                | 43   |

Data sources: [92, 259, 260]

An investigation was conducted to study the hypergolicity of selected DCAs, e.g. commercially available [Bmim][DCA], and the AFRL developed AF-IL-617, with common oxidizers [261]. Diluents, particularly water and methanol, were introduced into the

fuel in an effort to understand the effect of dilution on the ignition delay. The water dilution limit at which ignition would still occur was obtained for the two DCA-based fuels with WFNA. Controlled droplet experiments were conducted with high-speed photography at 1040 frames/s to establish the ignition delays. A single run consisted of dispensing a small droplet of fuel into a cuvette with typically 250 or 500  $\mu\text{L}$  of oxidizer. The bulk of the testing focused upon two work-horse DCA-based fuels: [Bmim][DCA] (BMIMDCA) and AF-IL-617. BMIMDCA is commercially available, and AF-IL-617 was developed in-house at the AFRL. The oxidizers of interest were WFNA, HAN, S-HAN-5, dinitrogen tetroxide, and 93% hydrogen peroxide. The experiment utilized a syringe pump with a 10- $\mu\text{L}$ , glass hypodermic syringe to dispense the fuel droplet into the pool of oxidizer in a cuvette 4.6 cm below. The drop test was recorded at 1040 frames/s with a monochrome high-speed digital camera.

A new class of RTILs that can ignite hypergolically with WFNA was tested [97, 98]. Fast ignition of DCA ILs when mixed with nitric acid was different from the reactivity of the IL azides, which showed high reactivity with nitric acid, but did not ignite. Rapid-scan FTIR spectroscopy of the pre-ignition phase indicated the evolution of  $\text{N}_2\text{O}$  from both the DCA and azide RTILs. There was evidence for the evolution of  $\text{CO}_2$  and  $\text{HNCO}$  with similar temporal behavior to  $\text{N}_2\text{O}$  from reaction of the DCA ILs with nitric acid. Evolution of  $\text{HN}_3$  was detected from the azides. No evolution of  $\text{HCN}$  from the DCA reactions was detected. From the FTIR observations, biuret reaction tests, and *ab initio* calculations, a mechanism was proposed for the formation of  $\text{N}_2\text{O}$ ,  $\text{CO}_2$ , and  $\text{HNCO}$  from the DCA reactions during pre-ignition. For the DCA-based ILs, the anion is responsible for inducing the ignition, while the cation may play only a secondary role in influencing the ignition delay time.

IL hypergolic fuels are already safer than many of the hypergolic fuels they are intended to replace, but they are still liquids that can leak. To make the fuels even safer and leak-proof, they can be gelled. Unfortunately, the increased viscosity causes longer ignition delays. The spray formation, atomization, mixing, and hypergolic ignition of gelled IL and the ignition of liquid and gelled methylethyl imidazolium DCA with nitric acid were tested [262, 263]. Sprays of propellant ignited in an ambient-pressure, optically accessible chamber, and high-speed video and optical sensors provided data on the speed of ignition events.

ILs derived from combinations of alkylammonium, hydrazinium, guanidinium, and hydrazidinium cations with DCA anions were tested for their reactivity toward hypergolic oxidizers [41]. This particular publication is a very thorough description of synthesis efforts to develop IL hypergolic fuels, with 47 literature references. For synthesizing a combustible IL with fuel qualities, the frequently used anions, nitrate, perchlorate, or dinitramide, had to be replaced with a combustible anion like DCA ( $\text{N}\equiv\text{C}$ ) $_2\text{N}^-$ . In looking for alkyl groups in alkylamines that are likely to react hypergolically with WFNA, a variety of primary, secondary and tertiary amines with alkenyl (vinyl or acryl) or alkynyl (propargyl) groups were prepared and their DCA salts prepared and tested. It was known that  $\text{C}=\text{C}$  bonds, such as those in

furfuryl alcohol or vinylisobutyl ether, promote hypergolic ignition. About half of the materials were RTILs with melting points ranging between 269 and 301 K (−4 and 28 °C). Most of the liquids had acceptably low viscosities between 26 and 120 cPs. Table 4 gives a summary of some of the salts investigated. Unfortunately, several of the unsaturated compounds had a tendency undergo cyclization reactions and formed heterocyclic-ring compounds with less desirable properties.

**Table 4:** ILs evaluated as hypergolic fuels.

Data source: [41]

Guanidinium and mono-, di-, or triaminoguanidinium dicyanoamides had melting points above room temperature, but three of the four salts had melting points below 373 K (100 °C) (Table 5). The DCA anion was chosen not only because it is a fuel-rich anion but also because IL dicyanoamides have some of the lowest viscosities among known ILs. Only a few of the DCA ILs ignited hypergolically with WFNA. It was proposed that the tests be repeated with IRFNA instead of WFNA and to also test with HTP. It was not possible to identify the “magic trigger group” that causes all IL fuels to become hypergolic fuels. See also [264].

**Table 5:** Properties of guanidinium dicyanoamides.

| Compound                         | Melting point |     | Decomp. onset |     | Density<br>g/cm <sup>3</sup> |

Data source: [265]

Imidazolium-based ILs were first considered because they generally possess greater stability than their triazolium or tetrazolium analogs. Unsaturated side chains, such as allyl, propargyl, and 2-butenyl, were selected because it was hoped that they would initiate or promote hypergolic ignition [92, 266]. It has been demonstrated in the past that unsaturated, especially acetylenic, compounds show a tendency to hypergolicity and can even be used as fuel additives to promote hypergolic ignition. Examples are furfuryl alcohol and Visol-1 (isobutylvinylether). 1-R-3-methylimidazolium DCAs with unsaturated R side chains were prepared and tested for hypergolic ignition with WFNA and RFNA. The physical properties and ignition delays are summarized in Table 3. Most substituted imidazolium DCAs are true room-temperature liquids.

Bipropellant ILs that react hypergolically with WFNA were tested to gain a fundamental understanding of the ignition of EILs with WFNA [247]. The effects of cation and anion structure on initiation reactions, and subsequent reactions leading to ignition for representative compounds in three classes of compounds (amino-1,2,4 triazoles, amino-1,2,3-triazoles and amino-tetrazoles) were investigated. In order to explain the effects of substituents, the decomposition products and their temporal evolution over a range of temperatures were analyzed. To gain further insight into the mechanism of decomposition, simplified kinetic models were developed and overall kinetic parameters were derived. The second major research objective was to study the hypergolic reaction mechanism for DCA-based ILs by analyzing the species produced during hypergolic ignition. A postulated key intermediate was dinitrobiuret. Another intermediate is HNCO.

ILs with the DCA anion have been shown to exhibit hypergolic properties and instantaneous ignition when in contact with WFNA. Such liquids tend to have low volatilities, and high thermal and chemical stabilities, and often exhibit wide liquid ranges; this could allow utilization of these substances as bipropellant fuels in a variety of environmental conditions [267, 268]. Dicyanoborates with substituted *N*-acyclic, *N*-cyclic, and azolium cations can be synthesized in water.

A new class of hypergolic ionic salts with the 2,2-dialkyltriazanium cation was reported to be capable of igniting rapidly with WFNA [269, 270]. 2,2-Dimethyltriazanium nitrate (**I**) displayed the shortest ignition delay time of 4 ms but, unfortunately, it is a solid at room temperature and it does not melt until it is heated to 372 K (99 °C).

When the 2,2-dialkyltriazanium cation was used in combination with the nitrocyanamidate (**II**) instead of the nitrate anion, the resulting IL turned out to be a true liquid at room temperature (m.p. = 273 K = -0.2 °C) and also exhibited excellent hypergolic properties. For example, when WFNA or N<sub>2</sub>O<sub>4</sub> was used as the oxidizer, the ignition delay time of this IL was 16 and 8 ms, respectively.

Fourteen *N,N*-dimethylhydrazinium DCA and nitrocyanamidate ILs were prepared by quaternization of *N,N*-dimethylhydrazine (UDMH) with alkyl halides, followed by metathetical reactions with silver DCA or silver nitrocyanamidate [91]. The key physicochemical properties, such as melting point and decomposition temperatures, density, viscosity, heat of formation, detonation pressure and velocity, and *I*<sub>sp</sub>, were measured and/or calculated to study the impact of anions and alkyl-substituted hydrazinium cations on these properties. Droplet ignition delay tests with WFNA as the oxidizer showed that these new *N,N*-dimethylhydrazinium salts were hypergolic, with ignition delay times ranging from 22 to 1642 ms. Of these, *N,N,N*-trimethylhydrazinium DCA and *N,N,N*-trimethylhydrazinium nitrocyanamidate gave ignition delays of 58 and 126 ms, respectively. The replacement of -NH<sub>2</sub> with a methyl group in the cation resulted in the significant increase in the ignition delay time, i.e. 16 versus 126 ms, indicating that the structure of two or three adjacent nitrogen atoms in the cation is favorable for the shorter ignition delay time of hypergolic ILs.

It was attempted to use DFT tight-binding MD (DFTB-MD) simulations to study the initial stages of hypergolic reactions between an EIL and nitric acid [271, 272]. Calculations were performed at various temperatures, and various reaction mechanisms were identified. The reaction products, such as H<sub>2</sub>O, HNCO, and CO<sub>2</sub>, predicted by DFTB-MD simulations were in agreement with the experiments reported by the AFRL.

The reaction mechanism is very complex and it changes with temperature. The energy gap between the highest occupied molecular orbitals (HOMO) of anions and the lowest occupied molecular orbitals (LUMO) of  $\text{HNO}_3$  was used as a parameter for interaction between a base and an acid. Based on molecular orbital calculations, a design guideline for hypergolic ILs was developed [273].

The QSPR represents a simplified design approach for quantitatively predicting the ignition delay times based on linear correlations using a set of descriptors, which define electrostatics, H-bonding, and other structural features of the ILs [274]. Experimental ignition delay times for a set of 41 ILs were collected for QSPR development. Experimental measurements of the ignition delay times were then correlated to theoretical descriptors determined from quantum mechanical calculations. A number of multi-descriptor linear equations were analyzed by regression of the ignition delay data, showing reasonable agreement. The ignition delay values were observed to spread over a wide range, in large part due to the presence of oxygen in the fuel molecule. A brief overview of ILs as hypergolic fuels is provided in a series of lecture slides from an Advanced Energetic Materials Synthesis Workshop held in 2011 [275].

It was found that reactions between DCA-based ILs, e.g. [Emim][DCA] or [Bmim][DCA] and WFNA, always yielded a precipitate that was composed of cyclic triazines including melamine and its polymers [99, 276]. Indication was that about 25% of the IL was converted into the precipitate during the ignition. Evidence showed that polymerization occurred even at lower concentration of reagents (e.g. the reaction of DCA with aqueous  $\text{HNO}_3$  solution), when neither hypergolic ignition nor notable heating of the reaction mixture took place. Electrospray ionization MS showed that, during the hypergolic reaction, the  $\text{HNO}_3$  and IL cation (e.g.  $\text{Emim}^+$ ) first undergo an ion exchange, i.e.  $\text{Emim}^+$  pairs with  $\text{NO}_3^-$  to form water-soluble [Emim][ $\text{NO}_3$ ] and  $\text{HN}(\text{CN})_2$ , followed by the rapid self-polymerization of  $\text{HN}(\text{CN})_2$  to yield a precipitate (melamine and its oligomers) under conditions of instant high temperature and strong acidic environment.

Hypergolic ignition of two hypergolic ILs [Emim][DCA] and [Bmim][DCA] was tested with three oxidizers (WFNA, RFNA, and NTO) [277]. A drop test system was designed to control the collision event of a single droplet of fuel with an oxidizer pool in a reproducible way. The results showed that the hypergolic ignition process of [Emim][DCA] with WFNA is quite similar to that of MMH–WFNA. Combined with thermophysical properties of hypergolic ILs, a mechanism for the hypergolic ignition process of [Emim][DCA] – WFNA was proposed. Hypergolicity of different propellant combinations was tested to investigate the influence of the oxidative capacity of oxidizers and the cation structure of ILs.

The low vapor toxicity of ILs make them attractive replacements for hydrazine in rocket applications. However, ILs will fail to fulfill their promise unless toxic hypergolic oxidizers like  $\text{HNO}_3$  or  $\text{N}_2\text{O}_4$  can be replaced with safer alternatives. By their very nature, all rocket oxidizers are hazardous and so, reducing the hazards, even though the resulting materials might not be completely harmless, is at the heart of green initia-

tives in propulsion. A significant step to a lower toxicity bipropellant system would be the demonstration of hypergolicity (spontaneous ignition) between an IL and a safer oxidizer like hydrogen peroxide. Outside of cryogenics, hydrogen peroxide seems to be promising, with its less toxic vapor and corrosivity and its environmentally benign decomposition products. Up until 2011, no IL had been reported to be reliably hypergolic with  $\text{H}_2\text{O}_2$ , but additional work is in progress [278, 279]. A number of imidazolium ILs with azide, cyanamdate, nitrocyanamdate, and boranate anions and adducts with aluminum boranate were tested with 90 and 98%  $\text{H}_2\text{O}_2$ , but ignition was very slow, of the order of several seconds, if it ignited at all.

A selection of substituted imidazolium cations was prepared and paired with known hypergolic anions (DCA) and more recently employed anions (vinylgous DCA and  $N,N'$ -dicyanoformamidinate) in the synthesis of ILs that might be useful as hypergolic fuels [280].

1-Butyl-3-methylimidazolium tetrafluoroborate, which is not hypergolic with WFNA by itself, could be hypergolized by dissolving nitrogen–boron compounds in the IL [281]. The solids ammonia borane (a), hydrazine borane (b), and hydrazine bis(borane) (c) were all found to exhibit hypergolic behavior with WFNA with ignition delays of 80, 4, and 12 ms, respectively. They are soluble in 1-butyl-3-methylimidazolium tetrafluoroborate. Dissolving ammonia borane or hydrazine borane in the non-hypergolic IL resulted in hypergolic solutions (ignition delays of 88 and 390 ms with WFNA, respectively). ILs containing the DCA anion instead of the tetrafluoroborate anion were also good solvents for the three B–N compounds and reacted hypergolically with WFNA. Dissolving boranes in the DCA liquids reduced the ignition delays of the ILs significantly, with values ranging from 3 to 34 ms.

A detailed chemical kinetics model has been built to examine the gas-phase chemistry between  $\text{HNCO}$ , WFNA,  $\text{N}_2\text{O}$ ,  $\text{CO}_2$ , and water at low-to-medium temperatures (ambient to 423 K) [282, 283]. This kinetics model was supposed to explain the gas-phase ignition observed during hypergolic ignition of the IL  $[\text{Bmim}][\text{DCA}]$  with WFNA. Ignition is predicted to occur via an exothermic reaction between  $\text{HNCO}$  and nitric acid ( $\text{HONO}_2$ ), and subsequent  $\text{HONO}_2$  thermal decomposition that has  $\text{NO}_2$  and  $\text{OH}$  radicals as the primary chain carriers. A detailed understanding of the initiation processes in the liquid phase is needed, as the  $[\text{Bmim}][\text{DCA}]$  and WFNA begin to react to produce the above pre-ignition species for the proposed chemical kinetics model to describe the ignition behavior of the system.

Hypergolic bipropellant fuels that are self-igniting with  $\text{N}_2\text{O}_4$  as the oxidizer can be made from protonated alkylhydrazides, carbohydrazide, or di- and triaminoguanidinium as the cation, and DCA or TCM as the anion [264]. Details about these ILs are summarized in *Encyclopedia of Liquid Fuels*, chapter “Amides and Imides.”

MD simulations of mixtures of the RTILs  $[\text{Bmim}][\text{DCA}]$  and  $[\text{Bmim}][\text{NO}_3]^-$  with WFNA have been performed utilizing quantum chemistry computations [284]. Experimentally, it has been observed that  $[\text{Bmim}][\text{DCA}]$  exhibits hypergolic behavior when mixed with  $\text{HNO}_3$  while  $[\text{Bmim}][\text{NO}_3]^-$  does not. The structural, thermodynamic, and

transport properties of the IL/ $\text{HNO}_3$  mixtures have been determined from equilibrium MD simulations over the entire composition range (pure IL to pure  $\text{HNO}_3$ ) based on bulk simulations. Additional (non-equilibrium) simulations of the composition profile for IL/ $\text{HNO}_3$  interfaces as a function of time have been utilized to estimate the composition-dependent, mutual-diffusion coefficients for the mixtures. The latter have been employed in continuum-level simulations to examine the nature (composition and width) of the IL/ $\text{HNO}_3$  interfaces on the millisecond time scale.

Similar quantum chemistry-based force field calculations have been performed for the hydrazinium, methylhydrazinium, and dimethylhydrazinium cations in combination with the nitrate, azide, DCA, or 5-azidotetrazolate anions [285]. Calculations were performed on the neutral precursors, ions, and cation–anion complexes. Seven different ionic systems have been investigated:  $\text{N}_2\text{H}_5\text{NO}_3$ ,  $(\text{CH}_3)_2\text{N}_2\text{H}_4\text{NO}_3$ ,  $(\text{CH}_3)_2\text{N}_2\text{H}_3\text{NO}_3$ ,  $\text{N}_2\text{H}_5\text{CN}_7$ ,  $(\text{CH}_3)_2\text{N}_2\text{H}_4\text{N}_3$ ,  $(\text{CH}_3)_2\text{N}_2\text{H}_3\text{N}_3$ , and  $\text{N}_2\text{H}_5\text{N}(\text{CN})_2$ . For all of these, except  $(\text{CH}_3)_2\text{N}_2\text{H}_3\text{NO}_3$  and  $\text{N}_2\text{H}_5\text{N}(\text{CN})_2$ , calculations of a single, gas-phase ion pair predicted spontaneous deprotonation of the cation. Crystal-lattice parameters obtained from MD simulations were compared with experiments for ionic crystals of these seven systems, with the experimentally determined crystal structure of  $\text{N}_2\text{H}_5\text{N}(\text{CN})_2$  as an example, which enabled comparison of the simulation and experiment for this compound.

In a very thorough re-evaluation of a wide range of heterocyclic amine cations and various anions previously shown to impart hypergolicity to ILs, a total of 13 halide salt precursors were synthesized through typical quaternization reactions between the neutral heterocycles and respective alkylating agents such as iodomethane, chloroethane, 1-chlorobutane, 1-bromobutane, 1-chloro-2-methoxyethane, allyl chloride, or propargyl bromide [286, 287]. Typical quaternization reactions were conducted by first dropwise adding 1.1 mol excess of the alkylating agent under a constant stream of argon to a round-bottom flask containing the pure heterocycle while stirring at 273 K (0 °C). The reaction mixture was then slowly heated to a gentle reflux for between 24 and 96 h and monitored by  $^1\text{H}$ -NMR until no unreacted heterocycles could be detected. Saturated solutions of the halide precursors in methanol were added to the suspensions of a 1.1 mol excess of the corresponding silver salt delivering the anion. The mixtures were then allowed to stir at 298 K (25 °C) for at least 3 days. The metathesis reactions were monitored via  $^1\text{H}$ -NMR by observing the upfield shift of the azolium peaks until only a single set of cation peaks was present. A total of 38 salts (32 liquids and 6 solids) were isolated from 13 cations and 3 anions and characterized by IR and NMR. Upon the removal of excess silver salts, each isolated IL was extensively dried under high vacuum ( $\sim 1 \times 10^{-4}$  mm Hg) while being stirred and heated at 323–343 K (50–70 °C) for between 7 and 10 days. Additionally, each salt was freeze-thawed 3 times to remove any entrapped gases and trace amounts of volatiles. Melting points or glass-transition temperatures for the combinations of 13 amines (11 five-membered and 2 six-membered heterocyclic amines) and three anions were tabulated. Each salt was characterized by DSC and TGA to determine melting temperature ( $T_m$ ), glass-tran-

sition temperature ( $T_g$ ), and onset of thermal decomposition, which were assembled in a table. The highest melting points were observed for salts of the same cation with azide anions. The lowest-melting IL ( $T_m = -55^\circ\text{C}$ ) was *N*-butyl-*N*-methyl-pyrrolidinium DCA. Many of the salts were hygroscopic and it was difficult to remove the last traces of water. Although 32 liquids were obtained, 14 of these exhibited no observable melting or glass transitions, which might be a result of the hygroscopic nature of these compounds. Even trace amounts of water could interfere with a glass or melting transition. Viscosity, density, and ignition delay with WFNA of 12 ILs were measured and tabulated. Ignition delays ranged from 19 to 151 ms. Surprisingly, the IL that had the lowest ignition delay was 1-propargyl-3-methyl-imidazoliumDCA, with a value of only 19 ms, although it had the second-highest reported melting point of any of the DCA-based ILs ( $290\text{ K} = 17^\circ\text{C}$ ) and a moderately high viscosity (31.7 cPs). The same functional group that promoted faster ignition (19 ms) also contributed to a higher viscosity (31.5 cPs), higher melting point ( $290\text{ K} = 17^\circ\text{C}$ ), and lower thermal stability ( $470\text{ K} = 197^\circ\text{C}$ ). All allyl-substituted cations had ignition delays of 31 ms or less.

Many ILs containing the DCA anion exhibit hypergolic ignition when exposed to WFNA. However, the ignition delay is often about 10 times longer than the desired 5 ms for rocket applications, so that improvements are needed. Experiments have suggested both a mechanism for the early reaction steps and also that additives such as decaborane can reduce the ignition delay. The mechanisms for reactions of nitric acid with both  $\text{DCA}^-$  and protonated DCAH were examined using accurate wavefunction quantum chemical computational methods [101]. Complexation of  $\text{DCA}^-$  or DCAH with borane clusters  $\text{B}_{10}\text{H}_{14}$  or  $\text{B}_9\text{H}_{14}^-$  was found to modify these mechanisms slightly by changing the nature of some of the intermediate saddle points and by small reductions in the reaction barriers.

The transport properties of DCA ILs are significant for their applications as solvents, electrolytes, and hypergolic fuels in bipropellants. Several transport properties of four DCA ILs ( $[\text{C4mim}][\text{N}(\text{CN})_2]$ ,  $[\text{C4m2im}][\text{N}(\text{CN})_2]$ ,  $\text{N4442}[\text{N}(\text{CN})_2]$ , and  $\text{N8444}[\text{N}(\text{CN})_2]$ ) including viscosity, conductivity, and electrochemical property at different temperatures were examined and related to the chemical structure of the ionic salts [288]. The melting points, temperature-dependent viscosities, and conductivities revealed the structure–activity relationship of four DCA ILs. From the Walden plots, the imidazolium cations exhibit stronger cation–anion attraction than the ammonium cations. DCA ILs have relatively high values of electrochemical windows, which makes them potential candidates for electrolytes in electrochemical applications. The electrochemical properties of the DCA ILs are dominated by the cationic structures. A correlation of the cationic structure–transport property relationships of DCA ILs was developed, which will be useful for designing new functionalized ILs to fulfill specific requirements. See also [236, 289].

Ignition delays of three DCA-based ionic liquids with different cations, 1-allyl-3-methyl imidazolium ([Amim]), 1-ethyl-3-methylimidazolium ([Emim]) and 1-butyl-3-methyl-imidazolium ([Bmim]) with WFNA were measured in a single droplet test

apparatus [290]. The experimental results indicated that short-chain alkyl and unsaturated alkyl substituents in cations are favored for short hypergolic ignition delays.

The ignition delays of two EILs (1-butyl-1-methylimidazolium dicyanamide,  $\text{Bmim}^+\text{DCA}^-$ ) and 1-butyl-1-methylpyrrolidinium dicyanamide ( $\text{Bmpy}^+\text{DCA}^-$ ) with WFNA were measured in a 100%  $\text{N}_2$  atmosphere and then again in a 25%  $\text{N}_2\text{O}$  and 75%  $\text{N}_2$  atmosphere [291]. The addition of  $\text{N}_2\text{O}$  was found to decrease the average ignition delays for both EILs.

### 12.2.2 ILs with Nitrodicyanomethanide Anions as Hypergolic Fuels

Twelve IL salts with nitrodicyanomethanide and dinitrocyanomethanide anions paired with 1,5-diamino-4-methyltetrazolium, 1,4-dimethyl-5-aminotetrazolium, 1,4,5-trimethyltetrazolium, 1-methyl-4-amino-1,2,4-triazolium, 1,4-dimethyltriazolium and 1,3-dimethylimidazolium cations have been prepared through metathesis reactions of equivalent silver(I) salts with corresponding iodide salts in acetonitrile [292]. The relationships between key physical properties, such as melting point, thermal stability, and density and their structures were examined. The structures of 1,5-diamino-4-methyltetrazolium-based salts were further confirmed by single-crystal XRD. The densities and standard enthalpies of formation were calculated. All of the salts had higher enthalpies of formation than the nitrate analogs.

### 12.2.3 ILs with Boron-Containing Anions as Hypergolic Fuels

Tri(hexyl)-tetradecyl-phosphonium tetraboranoaluminate  $(\text{C}_6\text{H}_{13})_3(\text{C}_{14}\text{H}_{29})\text{P}^+\text{Al}(\text{BH}_4)_4^-$  or oxygen-balanced 1-ethyl-4,5-dimethyltetrazolium tetranitratoaluminate  $\text{Al}(\text{NO}_3)_4$  will react hypergolically with 98%  $\text{H}_2\text{O}_2$  [293].

A series of hypergolic CTB anion-based ILs was synthesized by a straightforward N-hydroboration of tetrazole followed by a salt metathesis reaction [121]. The salts exhibited remarkably low viscosity ( $<20\text{ mPa}\cdot\text{s}$ ), high density (often  $>1.1\text{ g/cm}^3$ ), and ultra-short ignition delay time (as short as 1.4 ms) upon contact with WFNA.

A series of hypergolic ILs based on the cyano(1*H*-1,2,3-triazole-1-yl) dihydroborate anion were synthesized by introducing the  $[\text{BH}_2\text{CN}]$  moiety into the 1,2,3-triazole anion [294]. This introduction improved the hypergolic ignition property and decreased the viscosity of IL fuels. The synthesized series of hypergolic ILs exhibited wide liquid operating ranges ( $>220^\circ\text{C}$ ), high densities ( $>1\text{ g/cm}^3$ ), low viscosities (as low as 23 cPs), and ignition delay times as short as 5 ms by WFNA as the oxidizer. These ILs can also be ignited upon contact with a 90 mass-%  $\text{H}_2\text{O}_2$  oxidizer in the presence of a trace of iodine. See also [253, 295].

### 12.2.4 ILs with Tetrahydroborate Anions as Hypergolic Fuels

A series of pure  $\text{BH}_4^-$  ILs with 1-butyl-2,3-dimethylimidazolium (Bmmim), 1-ethyl-3-methylimidazolium (Emmim), 1-propyl-1-methylpiperidinium (PropMPip), and 1-butyl-1-methylpyrrolidinium (BMP) cations were prepared [265]. All synthesized ILs

were well soluble in  $\text{CH}_2\text{Cl}_2$ . A facile route to  $[\text{B}_3\text{H}_8]^-$  ILs with  $\text{Bmmim}^+$ ,  $\text{Emmim}^+$ ,  $\text{PropMPip}^+$ , and  $\text{NBu}_4^+$  was developed, in which  $\text{Na}[\text{BH}_4]$  reacts *in situ* (enhanced by ultrasound) with the solvent  $\text{CH}_2\text{Cl}_2$  as the oxidizing agent to give the triborate IL in high yield and purity according to the equation:

This reaction path was further investigated by additional NMR spectroscopic experiments, powder-XRD analysis, and quantum chemical DFT calculations.

Borohydride ILs and borane–IL solutions meet nearly all of the desired important criteria for well-performing hypergolic non-toxic fuels [296]. Ignition delay times are superior to those of any known hypergolic IL and may thus be possible replacements for hydrazine, MMH, or UDMH as bipropellant fuels.

Borohydride-containing ILs have been synthesized using a more efficient synthetic pathway that does not require liquid ammonia and halide precursors [297]. Among the eight new compounds, 1-allyl-3-*n*-butyl-imidazolium borohydride and 1,3-diallylimidazolium borohydride exhibited very short ignition delay times of 8 and 3 ms, respectively. The borohydride ILs are viscous compounds. 1,3-Diallylimidazolium tetrahydroborate had the lowest viscosity at 175 mPa s and the shortest ignition delay of 3 ms. The hydrolytic stability of borohydride compounds has been greatly improved by attaching long-chain alkyl substituents to the imidazole ring. 1,3-Di-(*n*-octyl)-imidazolium tetrahydroborate is a water-stable borohydride-containing IL. 1,3-Di-(*n*-butyl)-imidazolium tetrahydroborate is a unique example of a borohydride liquid crystal. These ILs have some unusual advantages, including negligible vapor pressures, good ignition delay times, and reduced synthetic and storage costs, thereby showing good application potential as environmentally friendly fuels in bipropellant formulations. See also [298].

A series of *N*-alkylimidazole borane compounds with zwitterionic structure has been synthesized and characterized [251, 252]. The borohydride  $-\text{BH}_3^-$  group is attached to the carbon in the 2-position between the two nitrogen atoms in the imidazole ring. The positive charge oscillates in the ring between the nitrogen atoms. These compounds are potential hypergolic fuels owing to their excellent physicochemical properties including low melting points, high thermal stability, low viscosities, and unique hypergolic reactivity.

A family of hydrophobic borohydride-rich ILs was developed, one of which, *N*-allylpyridinium, exhibited the shortest ignition delay times of 1.7 ms and the lowest viscosity (10 mPa s) of hypergolic ILs, demonstrating their great potential as faster-igniting rocket fuels to replace toxic hydrazine derivatives in liquid bipropellant formulations [299]. Comparing the stabilities of previously reported ILs with hydrogen-rich anions, i.e. typical  $\text{BH}_4^-$  and  $\text{BH}_2(\text{CN})_2^-$ , partial replacement of negatively charged hydrogen atoms on the boron atom with electron-withdrawing cyano groups can significantly improve the water stability of the resulting hypergolic ILs. In the design strategy of borohydride-rich anions, creating a cyano-bridged

dicyanodiboranate anion  $[\text{BH}_3(\text{CN})\text{BH}_2(\text{CN})]^-$ , one cyano group can serve as a stabilizing ligand to bridge two hydrogen-rich  $\text{BH}_3$  and  $\text{BH}_2\text{CN}$  moieties, while both cyano groups as electron-withdrawing groups play a role in improving the chemical stability of negatively charged hydrogen atoms. Quaternized alkylimidazolium, pyridinium, and pyrrolidinium salts with the  $[\text{BH}_3(\text{CN})\text{BH}_2(\text{CN})]^-$  anion all had melting and glass-transition points between 251 and 236 K (–22 and –37 °C) and good thermal stability.

#### 12.2.5 ILs with Borane Cluster Anions as Hypergolic Fuels

Nonaborane and decaborane cluster anions  $[\text{B}_9\text{H}_{14}]^-$  and  $[\text{B}_{10}\text{H}_{13}]^-$  can form stable solutions in ILs or certain molecular solvents, leading to enhanced ignition in known hypergols (fuels that spontaneously ignite upon contact with an oxidizer), or induced hypergolicity in certain non-hypergolic solvents [300, 301]. It was attempted to achieve hypergolic ignition between 1-methyl-3-sulfoimidazolium nitrate as the oxidizer and [3-butyl-1-methylimidazolium] $[\text{B}_6\text{H}_7]$  as the fuel, and indeed they ignited [238].

The compounds described in the following sections are solids and do not belong in this section on ILs. They are just mentioned here because the mechanisms leading to hypergolic ignition are similar to those observed with ILs. Imidazole-substituted decaborane, 6-exo,9-exo-bis(imidazole) decaborane, was used as a hypergolic “trigger” component in combination with energy-rich but non-hypergolic nitrobenzene or pyrazine to create hypergolic co-crystals [302]. Other hypergolic solids were made from metal–organic frameworks [303].

Closo-dodecahydroborate salts with guanidinium-and aminotetrazolium-based cations were synthesized, crystallized, and characterized, but they have high melting points, all above 497 K (224 °C) [304]. The salts were readily produced in good yields by metathesis (ion exchange) reactions, depending on the water solubility of the dodecahydroborate salts. Water-insoluble salts were synthesized from the potassium or sodium salts by a simple metathesis reaction with the corresponding halide of the desired organic cation. Water-soluble salts were prepared via two consecutive metathesis reactions: the halide was first converted to the corresponding sulfate, which, in turn, was reacted with barium dodecahydroborate, yielding the water soluble organic closo( $\text{B}_{12}\text{H}_{12}$ ) $_2^-$  salt and the insoluble  $\text{BaSO}_4$ . The thermal stabilities of these compounds were established by TGA. The enthalpies of combustion of representative salts were determined using constant-volume bomb calorimetry. The data showed that these salts possess relatively high heats of combustion ( $\Delta U_c$ , ca. 35 kJ/g), and have the potential to serve as green high-energy materials.

#### 12.2.6 ILs with Other Boron-Containing Anions as Hypergolic Fuels

Tetrahydroborate anions can be combined with other anions in an effort to lower the freezing point and viscosity of ILs. Phosphorus is not a preferred element to have in rocket fuels, but boranophosphate ILs have been evaluated as hypergolic rocket fuels [255].

From a rocket performance standpoint, it is not a good idea to replace hydrogen in boranate anions with iodine but, apparently, this substitution which results in ILs of organic amines with periodoborane anions ( $[\text{B}_{12}\text{I}_{12}]^{2-}$ ) enables hypergolic reactions with hydrogen peroxide [305, 306].

### 12.2.7 ILs with Cyanoborate Anions as Hypergolic Fuels

To achieve very short ignition delay times, *N,N*-dimethyl-*N*-butylhydrazinium dicyanoboranate,  $[(\text{C}_4\text{H}_9)(\text{CH}_3)_2\text{NNH}_2]^+[\text{BH}_2(\text{CN})_2]^-$  and *N,N*-dimethyl-*N*-acrylhydrazinium dicyanoboranate  $[(\text{C}_4\text{H}_9)(\text{CH}_3)_2\text{NNH}_2]^+[\text{BH}_2(\text{CN})_2]^-$  ILs, all of which had low melting points of  $<353\text{ K}$  ( $<80^\circ\text{C}$ ), were designed and synthesized [307]. All these ILs were air- and water-stable and exhibited good thermal stability, and their onset of decomposition temperature was higher than  $473\text{ K}$  ( $200^\circ\text{C}$ ). More importantly, they exhibited relatively low viscosities of  $<40\text{ MPa}\cdot\text{s}$  and can also ignite rapidly with WFNA in 5 ms. In comparison with other hypergolic ILs, which contain the more common anions, e.g. DCA or nitrocyanamidate anions, these dicyanoborate-based ILs had lower or similar melting points, higher thermal stability, lower viscosities and, most importantly, much shorter ignition delay times.

Cyanoborohydride-(cyanoboranate)-based ILs have hypergolic ignition properties and performances comparable to hydrazine derivatives [308]. They have negligible vapor pressure, short ignition delay times, and tolerable synthesis and storage costs, thereby showing good application potential as environmentally friendly fuels in bipropellant rockets.

The oxidation of levitated 1-butyl-3-methylimidazolium dicyanoborate ( $[\text{Bmim}][\text{DCBH}]$ ) or 1-allyl-3-methylimidazolium dicyanamide ( $[\text{Amim}][\text{DCA}]$ ) droplets by  $\text{NO}_2$  vapor was monitored using FTIR, Raman, and UV-visible spectroscopic methods [102, 309, 310].

Furfuryl alcohol has been used as a solvent for an IL,  $[\text{Emim}][\text{BH}_3\text{CN}]$ , together in different volume proportions (80:20, 70:30, 60:40, 50:50, and 40:60), forming a hypergolic fuel [311]. The blends exhibited good stability (chemical and thermal), low viscosity ( $\eta < 15\text{ mPa}\cdot\text{s}$ ), high density ( $\rho > 1\text{ g/cm}^3$ ), short ignition delay, and high performance in comparison to UDMH.

Two hydrophobic imidazolylidene-cyanoborane complexes were prepared by reaction of imidazolium iodide with  $\text{NaBH}_3\text{CN}$  [116]. These two compounds were characterized using IR and  $^1\text{H}$ - and  $^{13}\text{C}$ -NMR spectroscopy, HR-MS, and XRD. The compound was hypergolic with WFNA and was immiscible with water, had a wide liquid range ( $T_g = 251\text{ K} = -22^\circ\text{C}$ ), short ignition delay time (13 ms), high density ( $0.98\text{ g/cm}^3$ ), and good density impulse ( $\rho I_{sp} = 347\text{ s g cm}^{-3}$ ).

### 12.2.8 ILs with Azide Anions as Hypergolic Fuels

Several imidazolium-based IL azides with saturated and unsaturated side chains were prepared and their physical and structural properties were investigated [312, 313]. The hypergolic ignition reactivity of these new as well as some previously

reported IL azides with  $\text{N}_2\text{O}_4$  and IRFNA was studied. With IRFNA and  $\text{N}_2\text{O}_4$ , all compounds reacted vigorously, with copious production of red fumes but without ignition. The initial heat release during these reactions did not result in hypergolic ignition of the material under the tested conditions.

Atomistic MD simulations were performed on the ILs [Bmim][ $\text{N}_3$ ], 1-butyl-2,3-dimethylimidazoliumazide [BMmim][ $\text{N}_3$ ], and 1-butynyl-3-methyl-imidazoliumazide [Bumim][ $\text{N}_3$ ] [314]. Good agreement between the experimentally determined and simulated crystal structure of [Bumim][ $\text{N}_3$ ] as well as the liquid-state density and ionic conductivity of [BMmim][ $\text{N}_3$ ] was achieved. Methylation of Bmim (yielding BMmim) resulted in dramatic changes in ion-structuring in the liquid and slowing of ion motion. Conversely, replacing the butyl group of Bmim with the smaller 2-butynyl group resulted in an increase of ion dynamics.

### 12.3 Other ILs as Hypergolic Fuels

ILs can contain dissolved metal salts, which catalyze decomposition of hydrogen peroxide and makes the fuel hypergolic with hydrogen peroxide [315]. Dissolving iodocuprate salts in [Emim] $^+$ [ $\text{H}_3\text{BCN}$ ] $^-$  and [mim][ $\text{BH}_3$ ] ILs produces fuels which are hypergolic with highly concentrated 95%  $\text{H}_2\text{O}_2$  oxidizer, with the ignition delay times down to 14 ms [316]. See also [231, 263, 274, 279, 317].

### 12.4 Amine Boranes as Hypergolic Fuels

Amine boranes may not qualify as ILs, but they are closely related to ILs with boron and nitrogen in their molecular structure [318]. A series of asymmetric monoimidazolium dihydroboronium-based ILs were synthesized from amine–boranes and characterized by  $^1\text{H}$ - and  $^{13}\text{C}$ -NMR and IR spectroscopy, elemental analysis, or HR-MS [319]. Compared with the symmetric bis(imidazolium)dihydroboronium-based ILs, these new ILs exhibited improved properties, with shorter ignition delay times, higher densities, and lower phase-transition temperatures.

A series of new amine borane/cyanoborane zwitterionic compounds was developed as hypergolic ILs [320]. The UDMH-based zwitterions, UDMH-borane and UDMH-bis(borane), displayed a strikingly lower ignition delay time of 2.2 and 2 ms, respectively, and a high  $I_{\text{sp}}$  of 241 and 245 s, respectively. The pyridinium–cyanoborohydride had a higher enthalpy of formation (146 kJ/mol) than UDMH. All the developed compounds had a higher density than UDMH. The chemical stability of UDMH-borane was investigated at different environmental conditions. It was found to be stable for longer duration. Short ignition delay, good thermal and chemical stability, positive heat of formation, high  $I_{\text{sp}}$ , ease of synthesis, and commercially available starting materials are some of the promising features of these compounds.

### 13 ILs as Working Fluids for Electric Propulsion

Colloidal thrusters are electrostatic accelerators of charged liquid droplets. One advantage of colloid engines for very small thrust levels is the fact that no gas-phase ionization is involved. Electrospray atomization delivers the small particle size required for efficient operation.

The negligible vapor pressure, substantial electrical conductivity, and thermal stability of ILs make them ideal candidates for electrospray space propulsion applications. An overview was provided covering current requirements in space propulsion, and it summarized the virtues of IL-propelled electrospray thrusters [321]. The physics associated with single cone-jet electrosprays was reviewed and recent developments with respect to IL ion sources were reported. Specific examples of MS measurements of charged particle emission from IL cone-jets included positive and negative ion emissions from [Emim][BF<sub>4</sub>], [Emim][Im], and [Emim][NO<sub>3</sub>].

ILs are suitable for electric space propulsion applications due to their high conductivity and negligible vapor pressure. The HAN-based AF-M315E is a promising monopropellant that has been successfully demonstrated for high-thrust chemical thruster operation. Dual-mode propulsion concepts in which AF-M315E would also be used for a high- $I_{sp}$  electrospray thruster operation are under evaluation. Quantum mechanical and classical MD calculations are being undertaken for likely ionic products of the AF-M315E propellant electrosprayed from an externally wetted tungsten emitter [322]. Quantum mechanical calculations determined that all assigned ion clusters observed experimentally are thermally stable at the operating temperature of 313 K. Proton transfer reactions occurring in the liquid phase of AF-M315E were found to play an important role in the observed ion distributions. Ionic clusters did not contain water or hydroxylammonium.

Chemical monopropellant and electrospray thrusters can both use ILs as propellants, lending themselves to the development of a dual-mode system. Several propellant candidates for a dual-mode electrospray-monopropellant micropropulsion system have been identified [323]. Reducing the number and size of hydrocarbon groups and increasing the highly electronegative species, such as oxygen and nitrogen, reduces the propensity of formation of solid carbon in the monopropellant exhaust. This also increases the surface tension and specific conductivity of the propellant, improving the thrust level for a given applied voltage in the electrospray mode.

### 14 Other Applications of ILs

There are many proposed new non-rocket applications for ILs, foremost being the battery electrolyte applications from which much of the research into ILs originated. Some of the knowledge gained about other applications of ILs may benefit their development as rocket propellants and vice versa [16]. The use of ILs as catalysts and/or solvents in synthesis reactions yielding high added-value products has also been pro-

posed. ILs can be coated in a thin layer on high-surface-area catalyst supports and serve as the medium in which reactions take place at an accelerated rate. These are called supported ILs [324]. ILs can also be used as working fluids for colloid thrusters. If we used them as conventional rocket fuels, they would be gone in a flash, in particular if they are a mix of a combustible fuel cation and an oxidizing anion. Most ILs are derived from the salts of heterocyclic amines.

### 14.1 EILs as Explosives

As is often the case, the propellant chemist trying to develop a more energetic rocket propellant is treading a thin line, easily overstepped, and can end up developing a liquid explosive instead. The story of ILs is no exception.

The US military is searching for replacements for TNT for use in melt-castable explosives. The AFRL has investigated the feasibility of replacing TNT with an IL (m.p.  $< 373\text{ K} = < 100\text{ }^{\circ}\text{C}$ ) [325]. The approach focused on synthesizing triazolium-based salts that have the appropriate physical and safety properties, thermal stability, and theoretical performance to potentially replace TNT. Individual salts selected from several families of energetic triazolium salts synthesized at the AFRL were shown to have high densities and relatively high heats of formation, and passed acceptance criteria of thermal stability tests.

The patent literature describes IL explosives consisting of eutectic mixtures of triazolium salts, such as 4-amino-1,2,4-triazolium perchlorate (4-ATP), 4-amino-1,2,4-triazolium nitrate (4-ATN), 1-H-1,2,4-triazolium perchlorate (TP), 1-amino-3-methyl-1,2,3-triazolium nitrate (1-AMTN) and 1-methyl-4-amino-1,2,4-triazolium perchlorate (MATP) [326]. Typical examples are eutectic mixtures of 4-ATP/4-ATN (70/30), 4-ATP/4-ATN (30/70) and 4-ATP/TP (30/70).

### 14.2 EILs as Gas Generants

Under a US Army STTR contract, C3 Propulsion, in cooperation with the Center for Green Manufacturing of the University of Alabama, proposed designing, developing, and demonstrating the feasibility of an on-demand gas generator, based on an IL monopropellant, that would supply pressures up to 24.1 MPa (3500 psi) and be suitable for pressurizing liquid and gelled fuel and oxidizer tanks in pressure-fed liquid-propellant missiles [327].

# Jet Fuels

## Introduction

The *Encyclopedia of Liquid Fuels* contains eight chapters dealing with hydrocarbon fuels. The topic of hydrocarbon fuels had to be subdivided into several smaller chapters that were easier to arrange in alphabetical order in five subvolumes of equal size. The titles of the eight hydrocarbon chapters are: “Alkanes,” “Alkenes and Alkynes,” “Aromatic Hydrocarbons,” “Cycloaliphatic Hydrocarbons,” “Hydrocarbons,” “Jet Fuels,” “Kerosenes,” and “Ramjet Fuels.”

## 1 Jet Fuels

This chapter on jet fuels, obviously fuels for air-breathing jet engines and not for rocket engines, may seem out-of-place in the *Encyclopedia of Rocket Propellants*, but there are so many similarities between jet fuel kerosenes and rocket engine fuel kerosenes that it is justifiable to include jet fuels here. The hydrocarbons are in many cases the same; it is just the composition of the mixtures that is different. Furthermore, analytical methods used for either type of fuel are the same. The same comments apply to ramjet fuels, which are described in a chapter of their own. Otherwise ramjet fuels would have been included here under “Jet Fuels.” Quite often jet fuels have been used as rocket fuels because they were readily available.

New types of jet propulsion, such as in rotating detonation engines and pulsejet engines, require unique hydrocarbon fuels, and the designers of those engines need a good source of physical properties of fuels to choose from.

The most frequently referenced set of specifications for hydrocarbon fuels is the one created by US military agencies for jet fuels described by the letters JP followed by a number designation (JP = jet propellant). JP-1 was the first kerosene propellant to be described by a specification. Neither JP-1 nor JP-2 found widespread application and the two specifications are now only of historical interest. JP-3 is a kerosene with a very wide boiling range. Because of its higher vapor pressure, its composition changes significantly if allowed to spend time in unpressurized fuel tanks in airplanes flying at high altitude; thus, it was only allowed to be used in airplanes that did not cruise at very high altitudes. The JP-3 specification was later replaced by JP-4 which has a lower vapor pressure and can be flown at higher altitudes. For many decades JP-4 was the most frequently used jet fuel in military aircraft.

Air/kerosene fuel mixtures are flammable and explosive. In spite of padding the tanks with “vitiated air” to lower the oxygen concentration, there have been 17 fuel tank ignition events on commercial airplanes since 1959 that have resulted in 542 fatalities and 11 airplane losses. On the military side, there have been 12 airplane losses

on the military version of the B-707 and the B-52. Both JP-4 and Jet A were gradually being replaced in the wake of an accident in a Boeing 747-131 commercial passenger plane on TWA flight 800 in 1996, where an unknown source of ignition caused one of the fuel tanks to explode in flight with a loss of life of all passengers and crew on board. Another loss of a B-52 bomber was caused by a lightning strike igniting fuel vapors in the tanks. Subsequently, fuels have been reformulated and efforts have been made to inert the vapor space above the fuel in the fuel tanks with nitrogen or vitiated air. Because JP-4 was widely available, many rocket engine tests have been conducted with JP-4 although it was not really intended as a rocket fuel, but only as a fuel for air-breathing jet engines.

JP-5 has a higher freezing point than JP-4 and a narrower boiling range, from 473 to 563 K (200 to 290 °C), compared to JP-4 (413 to 553 K = 140 to 280 °C). A similarly narrow boiling range is reported for RP-1 which is the main hydrocarbon fuel used in many US launch vehicles. For quick calculations, RP-1 can be assumed to have the gross formula  $C_{11.74}H_{21.83}$  and a mean molecular mass of 163 g/mol.

## 2 Jet Fuel Kerosene JP-4

The first turbojets flying after WW II used MIL-F-5616 (JP-1) fuel. However, it was quickly recognized that large fleets of jet aircraft operating under all-out emergency conditions would consume considerably more JP-1 fuel than would be available from crude petroleum with existing refinery equipment at that time. As a result, during the next several years, an intense effort was devoted to the development of a turbojet fuel specification that satisfied both performance as well as availability considerations. An original proposal for JP-3 fuel was made in January 1947. A second revision of the JP-3 specification was made in March 1949. The JP-3 specification remained unaltered until May 1951, at which time the mercaptan sulfur content was limited to a maximum of 0.005 mass-%. This revision was due to corrosion problems, possible rubber swell problems, and objectionable odors that were being encountered during engine tests. Considerable opposition to the high volatility of the fuel arose because of the excessive entrainment losses that occurred during rapid climb with vented tanks. A less volatile fuel obtained the designation JP-4. The change in Reid vapor pressure was accompanied by the elimination of the 90% distillation requirement and the addition of a maximum limit of 250 °F on the 10% distillation point. The limitation of the 10% point, in effect, placed a more precise restriction on the minimum volatility of the fuel, since the accuracy of the Reid vapor pressure determination is questionable at pressures as low as 13.8 kPa (2 psia). The change in volatility also required new specific gravity limits. In December 1953, the JP-4 specification was altered to eliminate the 10% and end-point requirements and to add limiting values on the 20, 50, and 90% points on the distillation curve [1].

JP-4, also known under the designation NATO F40, has been the most widely used fuel for air-breathing turbine jet engines for several decades, but between 1980 and 1991 it was gradually replaced by JP-8 which is a more narrow cut of kerosene distillates. The Military Specification described JP-4 as a “wide cut, gasoline type” fuel and marked it as “inactive for new design.” JP-4 is rarely used any more, although it is possibly still used in developing countries with less stringent requirements for quality of jet fuel.

There exists a large database on properties of JP-4, and although JP-4 is no longer in use, the literature on JP-4 is compiled here because a comparison of JP-4 with other grades of kerosenes is very educational. Thus, this section is mostly of historical interest. JP-4 is not going to be used any more as a rocket propellant in the U.S., but in the early years, in particular before the arrival of RP-1, numerous rocket engine tests were run with JP-4 as the kerosene fuel that was most readily available. A complete set of physical properties of JP-4 is useful. In some cases where more recent data are not available, one can extrapolate to properties of other kerosenes.

## 2.1 Production of JP-4

JP-4 and other kerosenes used as jet or rocket fuels are (were) processed from crude oil petroleum by distillation, desulfurization, and hydrogenation. Some JP-4 fuel blending stocks were hydrogen-treated to prevent the formation of gums and peroxides after manufacture.

## 2.2 Physical Properties of JP-4

There is a vast amount of data on physical properties of JP-4, but because the MIL-DTL-5642W (former MIL-F-5624C) tolerances for composition and other properties of JP-4 are fairly wide, the physical properties of a specific sample can vary widely as well. In some cases, properties of JP-4 derived from coal instead of petroleum were compared to those of traditional grades of JP-4. Physical properties of JP-4 are summarized in Table 1 and reference [2].

Although all fuel samples may have been within the fairly wide specification limits for JP-4, the properties of JP-4 supplied by refineries may have changed over the course of several years, depending on the source of petroleum and the methods of processing in the refineries. For several decades, the USAF Defense Fuel Supply Center (DFSC) collected and analyzed historical JP-4 samples from the field using 17 specification tests in order to identify trends in the composition and physical properties of this fuel, for instance [7].

Samples of JP-4, JP-5, and JP-8 were analyzed and new analytical methods were developed in support of programs for studying fuel combustion behavior, turbine en-

**Table 1:** Physical properties of JP-4.

gine design, and other fuel-related technologies [8]. Data obtained on most samples included hydrocarbon-type analysis (Modified ASTM D 2789 and Monsanto Method 21-PQ-38-63), simulated distillation (ASTM D 2887-73), heat of combustion (ASTM D 240-76), true vapor pressure, kinematic viscosity (ASTM D 445-79), surface tension (capillary rise method), and density. See also [9].

### 2.2.1 Density of JP-4

The range of density variations among several samples of JP-4 and their dependence on temperature is illustrated in Figure 1.

### 2.2.2 Vapor Pressure of JP-4

The vapor pressure of two different density (41 and 51 API) JP-4 samples was measured over the range from 311 to 644 K (100 to 700 °F) and the curve for the less volatile 41 API fuel is shown in Figure 2, with the Reid vapor pressure (RVP) as auxiliary variable [10]. The volume average boiling point for the API 41 fuel was 475 K (395 °F), and for the API 51 fuel it was 431 K (316 °F).

### 2.2.3 Viscosity of JP-4

The viscosity of JP-4 is illustrated in Figure 3 in comparison to that of JP-3 and JP-5. This is an average of many samples and one must expect significant variations from sample to sample.

Figure 1: Density of MIL-F-5624C (JP-4) fuel. (Reproduced and modified from [1].)

Figure 2: Vapor pressure of JP-4. (Republished and modified from [10], with permission of ©1954 American Institute of Aeronautics and Astronautics; permission conveyed through Copyright Clearance Center Inc.)

**Figure 3:** Kinematic viscosity of JP-4, JP-3, and JP-5. (Reproduced and modified from [1].)

Furthermore, the flow properties of JP-4 with entrained gas bubbles is different from those of a bubble-free liquid [11]. The dynamic viscosity of JP-4 at 298 K is 0.879 cPs.

#### 2.2.4 Surface Tension of JP-4

The surface tension of JP-4 at 300 K was reported as 23.27 mN/m = 23.27 dyn/cm [4].

#### 2.2.5 Thermal Conductivity of JP-4

The thermal conductivity of JP-4 at 300 K was reported as 0.14 W m<sup>-1</sup> K<sup>-1</sup> at 298 K = 0.079 BTU h<sup>-1</sup> ft<sup>-1</sup> °F<sup>-1</sup> at 77 °F [12].

#### 2.2.6 Heat Transfer Coefficient of JP-4

Heat transfer to subcritical JP-4 was studied using a transparent annular test section with an electrically heated, stainless steel tube [10]. Heat transfer data were obtained in the non-boiling, nucleate boiling, and film boiling regions for velocities from 0.9 to 12 m/s (3 to 40 ft/s) and pressures from 207 to 3447 kPa (30 to 500 psia). Burnout data were obtained over the same range of variables. The heat flux values were increased until either the tube failed or the limit of power generation was reached, which was approximately 1634 W/cm<sup>2</sup> (10 BTU in.<sup>-2</sup> s<sup>-1</sup>). The troublesome phenomenon of coking was studied visually and by the use of colored films. The dependence of the heat trans-

**Figure 4:** Effect of pressure and flow velocity on heat transfer to JP-4. (Republished and modified from [10], with permission of ©1954 American Institute of Aeronautics & Astronautics; permission conveyed through Copyright Clearance Center Inc.)

fer to JP-4 on pressure and flow velocity in a cooling channel in a rocket engine and the variation of nucleate boiling range with pressure is illustrated in Figure 4.

In the non-boiling regime of forced convection, the heat transfer to JP-4 can be represented by a Sieder–Tate equation with an accuracy of  $\pm 11\%$

$$Nu = 0.0213 Re^{0.8} Pr^{0.33} \left( \frac{\eta_m}{\eta_{wall}} \right)^{0.14}$$

where  $Nu$  is the Nusselt number,  $Re$  is the Reynolds number,  $Pr$  is the Prandtl number,  $\eta_m$  is the viscosity of the medium at the center of the flow and  $\eta_{wall}$  is the viscosity of the fluid near the wall. The transition from non-boiling heat transfer to nucleate boiling occurs at higher and higher pressures the lower the flow velocity is and vice versa.

In the regime of nucleate boiling, the influence of flow velocity is not as pronounced as the influence of pressure (see Figure 4, lower group of curves). The transition to film boiling, which is accompanied by a drop in heat transfer and can lead to burnout of the wall in critical locations at the upper limit of nucleate boiling, is not as strongly dependent on the local pressure.

## 2.2.7 Thermodynamic Properties of JP-4

### 2.2.7.1 Heat of Combustion of JP-4

There exists a wide variety of heat of combustion data for JP-4, depending on the source of the samples analyzed. The MIL SPEC requirement for the heat of combustion of JP-4 per MIL-DTL-5624W is a minimum of 42.8 MJ/kg (18413 BTU/lb). The NASA CEA input calculation for the enthalpy of formation of JP-4 (and RP-1) was based on a heat of combustion of 18640 BTU/lb [5]. One of the summary publications for kerosene properties [13] gives a heat of combustion of 18701.30 BTU/lb, which is the value accepted in reference [2].

The heating value of JP-4 and similar kerosenes is mostly a function of the hydrogen content of the fuel. The heating value can be estimated from an empirical equation

$$Q_{\text{net}} = 35.08 + 0.5849H$$

where  $Q_{\text{net}}$  is the heating value in MJ/kg and  $H$  is the hydrogen content in mass-%.

### 2.2.7.2 Enthalpy of Formation of JP-4

It is difficult to calculate the enthalpy of formation of a mixture of hydrocarbons that varies over such a wide range as JP-4 does. The enthalpy of formation is derived from the heat of combustion which varies just as much.

The standard enthalpy of formation of JP-4 was reported as  $-6124.80 \text{ cal/mol}$  for a molecular mass of  $14.027 \text{ g/mol}$ , which translates to a enthalpy of formation of  $-437 \text{ cal/g} = -1828 \text{ J/g}$  [13]. It is not meaningful to give enthalpy of formation of a mixture in terms of energy per mol because the molecular mass and empirical formula used by different investigators varies from case to case. Another source gave the enthalpy of formation of JP-4 as  $-1903 \text{ J/g} = -818 \text{ BTU/lb}$  [6]. However, the PEPCODED.DAT list gives an enthalpy of formation of  $-281 \text{ cal/g} = -1176 \text{ J/g}$  for a JP-4 fuel with a density of  $0.0254 \text{ lb/in.}^3 = 0.7031 \text{ g/cm}^3$ , which is quite different [14].

The NASA CEA input list [5] assumes a JP-4 enthalpy of formation of  $-22723 \text{ kJ/mol} = -1626.7 \text{ J/g} = -388.8 \text{ cal/g}$ , which is based on a heat of combustion of 18640 BTU/lb, assuming an empirical formula of  $\text{C}_{11}\text{H}_{1.9423}$  and a molecular mass of  $13.9688 \text{ g/mol}$  for a fuel with a density of  $0.773 \text{ g/cm}^3$ . This number is between that of [13] and [14]. They assume that the same data are valid for RP-1.

2.2.7.3 Enthalpy of Evaporation of JP-4

The latent enthalpy of evaporation of JP-4 and JP-5 as a function of temperature is illustrated in Figure 5.

Figure 5: Latent enthalpy of evaporation of JP-4 and JP-5. (Reproduced and modified from [1].)

2.2.8 Dielectric Constant of JP-4

The dielectric constant of JP-4 as a function of temperature is illustrated in Figure 6, based on the analysis of 30 samples, all within the specification limits of MIL-F-5624C. Measuring the dielectric constant of fuels is a tool for purity control and an indication

**Figure 6:** Dielectric constant of JP-4 as a function of temperature. (Reproduced and modified from [1].)

of the likelihood of building up dangerous electrostatic charges which may lead to accidental ignition in air.

## 2.3 Chemical Properties of JP-4

The empirical formula for JP-4 can be described as  $C_{9.5}H_{18.9}$  corresponding to a molecular mass of 133.1 g/mol. JP-4 was described as a high volatility, low freezing point fuel composed of approximately 65% gasoline and 35% kerosene.

### 2.3.1 Specifications for JP-4 and JP-5

The Military Specification for JP-4 is combined with that for JP-5. The most recent revision was MIL-DTL-5624W in 2016 [3]. As the last letter of the specification number indicates, this specification has gone through many revisions. The specification requirements for JP-4 are listed in Table 2.

**Table 2:** Specification requirements for JP-4 and JP-5.

| Property                                                                     | GRADE JP-4            | GRADE JP-5      | ASTM or IP test method                                                 |

<sup>a</sup> When using D6379 results, the higher maximum total aromatics limit shall apply

<sup>b</sup> If the visual rating of the heater tube shows peacock (P) or abnormal (A) type deposits, the fuel sample is not acceptable

<sup>c</sup> The thermal stability test shall be conducted using ASTM D3241 at a test temperature of 260°C.

The aromatic content of JP-4 has been historically quite low, around 11 vol.-%. Conversion from high volatility JP-4 to lower volatility JP-8, which is similar to commercial Jet A-1, as the primary USAF aircraft turbine fuel had been under consideration since 1978. The strong motives for the change were NATO standardization and reduced combat vulnerability. In addition, the crude oil strategic supply situation had led to considerations to determine the extent to which USAF fuel specifications can be broadened to increase the yield from available petroleum crudes and, ultimately, to permit production from other sources such as coal, oil shale, and tar sands or alcohol from fermentation.

Distillate hydrocarbon fuels are being considered for many hypersonic vehicle and space planes. Characterization of the composition of fuels is complicated by the relatively loose specifications and the variations encountered in the fuels from day-to-day and refinery-to-refinery. A version of ASTM D2425 was used to characterize a number of jet fuels from a recent world fuel survey, as well as a number of specialty kerosene fuels, such as RP-1 and JP-7 [15]. These data were useful for combustion physical property modeling, as well as developing “surrogates” for testing of kerosene fuels.

Additives found in JP-4 include MIL-PRF-25017 Inhibitor, Corrosion/Lubricity Improver, Fuel Soluble (NATO S-1747) and MIL-DTL-85470 Inhibitor, Icing, Fuel System, High Flash, (NATO S-1745).

Antioxidants are added to freshly processed JP-4 before the fuel is exposed to air during storage and transfer. Antioxidants are methyl-*tert*-butylphenols. The antioxidant concentration is limited to not less than 17.2mg nor more than 24.0mg of active ingredient per liter of fuel.

### 2.3.2 Surrogate Fuel Mixtures for JP-4

Because of the complexities involved in measuring and modeling the performance and properties of finished fuels, the fuel science community must often use surrogate mixtures as substitutes, especially in the absence of consensus standard mixtures. While surrogate mixtures are often formulated on the basis of the ability of a particular mixture to reproduce a particular property, there is usually a desire to employ surrogate mixtures that are physicochemically authentic. This means that, provided that the primary purpose is satisfied, researchers are inclined to choose mixtures that have physical and chemical properties appropriate to the finished fuel.

A mixture of 14 different, pure hydrocarbons was developed based on the distillation curve and compound class composition as a laboratory-reproducible surrogate fuel with properties very similar to those of JP-4 [16].

Two surrogate fuel mixtures were developed using a model-based optimizer to emulate the fuel properties affecting the spray development and gas phase ignition of a conventional jet fuel [17]. The first surrogate, UM1, was a mixture of *n*-dodecane/iso-cetane/methylcyclohexane/toluene (0.3844/0.1484/0.2336/0.2336 mol fraction), while the second, UM2, was a mixture of *n*-dodecane/iso-cetane/decalin/toluene (0.2897/0.1424/0.3188/0.2491 mol fraction). The surrogates contained hydrocarbon species that are available in existing chemical mechanisms, and emulate both the physical and chemical properties of a representative real jet fuel, Jet A POSF-4658. POSF-4658 is suitable as a surrogate target fuel since the properties of POSF-4658 are representative of a nominal Jet A, and a wide range of experimental POSF-4658 data is readily available, including multiple ignition delay measurements. While the UM1 surrogate gave a much tighter match for temperature-independent properties, UM2 was shown to better emulate liquid density and volatility, properties which are known to be important for spray predictions under engine conditions. Ignition delay times predicted with a detailed chemical mechanism under diesel conditions showed reasonable agreement with shock tube and rapid compression machine experiments.

### 2.3.3 Analysis of JP-4

The list of test methods for qualification of JP-4 (or JP-5) in MIL-DTL-5624W extends over 3½ pages [3]. Most of those test methods are documented ASTM test methods.

### 2.3.4 Thermal Stability of JP-4

During heat transfer measurements in the laboratory as well as in real airborne life application, carbon deposits as a result of incipient hydrocarbon decomposition will interfere with the heat transfer or clog passaged and increase pressure drops. Carbon deposits are good insulators and will reduce the amount of heat flowing through the wall. Pyrolysis of JP-4 and carbon deposition can start at wall temperatures of 753 to 923 K (480 to 650 °C), depending on the quality of the propellant [18].

Similar measurements and observations were made for JP-3 [19–22]. Carbon deposition can occur above 673 K (400 °C) and can become a real problem. Using the heat transfer data thus obtained in the laboratory, one can design and size a cooling system for LOX/JP-3 or N<sub>2</sub>O<sub>4</sub>/JP-3 rocket engines that are regeneratively cooled with JP-3 [23].

## 2.4 Toxicity of JP-4

Because the composition of JP-4 with and without additives may vary widely, depending on where the samples are taken, it is difficult to establish a safe limit for inhalation of JP-4 vapors at the place of employment [24]. The same concern applies to other kerosenes that are now replacing JP-4 in the inventory of military supplies. The recommended threshold limit value (TLV) for JP-4 is 2.5 mg/L.

Male and female Fischer-344 rats, female C57BL/6 mice, and male and female beagle dogs were divided into three treatment groups and exposed nearly continuously (23 h/day, 7 days/week) to JP-4 jet fuel vapor at concentrations of 0, 500, and 1000 mg/m<sup>3</sup> for 90 days [25]. At exposure termination, all dogs and 1/3 of the rodents were euthanatized and the remaining animals were held for either a 19- or 21-month post-exposure tumorigenesis observation period. Pathologic findings in male rats revealed treatment-related renal toxicity consistent with male rat oc2M-globulin nephropathy. No treatment-related respiratory toxicity was noted in any species. This study did not demonstrate target-organ toxicity or carcinogenesis which could be extrapolated to other species. A very detailed toxicological profile of JP-4 was published which also included toxicity data for JP-7 [26].

The relative potency of three jet fuels (JP-4, JP-8, and JP-8+100) to cause respiratory tract sensory irritation was studied by administering vapor only or vapor/aerosol mixtures for 30 min periods by means of a head-only exposure system to groups of four mice [27].

## 2.5 Environmental Impact of JP-4 Spills

Although JP-4 is no longer used, information on environmental impact of JP-4 spills is summarized here because similar consequences may be observed in the event of spills of other kerosenes, including RP-2. JP-4 and several other kerosenes were examined to measure the effects of potential environmental contamination resulting from these fuels on fresh water fish and aufwuchs [28]. Besides JP-4, the materials evaluated included RJ-4, RJ-5, methylcyclohexane, and JP-9. The toxicity of JP-4 would differ from that of other kerosenes if the additives turn out to be more toxic than the hydrocarbon base by itself. The water extract of the water-soluble fraction of JP-4 was still toxic to small fish [29, 30].

## 2.6 Safety Properties of JP-4

### 2.6.1 Flash Point of JP-4

The flash point of JP-4 can vary widely, depending on the exact composition of the fuel. It depends on the most volatile component of the hydrocarbon mixture that makes up JP-4 and similar jet fuels. The published flash point value for JP-4 is 244 K ( $-29^{\circ}\text{C} = -20^{\circ}\text{F}$ ) [6].

### 2.6.2 Flammable Range of JP-4 Vapors

The flammability limits of JP-4 and JP-5 are listed in Table 3.

**Table 3:** Flammability limits of JP-4 and JP-5.

| Fuel               | Flammability limits |      |                |      |
|--------------------|---------------------|------|----------------|------|
|                    | Volume percent      |      | Fuel:air ratio |      |
|                    | Lean                | Rich | Lean           | Rich |
| JP-4               |                     |      |                |      |
| Minimum volatility | 0.74                | 5.34 | 0.035          | 0.26 |
| Maximum volatility | 0.90                | 6.15 | 0.035          | 0.25 |
| Average volatility | 0.80                | 5.63 | 0.035          | 0.26 |
| JP-5               |                     |      |                |      |
| Minimum volatility | 0.57                | 4.38 | 0.035          | 0.28 |
| Maximum volatility | 0.62                | 4.68 | 0.035          | 0.28 |
| Average volatility | 0.60                | 4.53 | 0.035          | 0.28 |

Data source: [1]

### 2.6.3 Autoignition Temperature of JP-4

The autoignition temperature of flammable liquids is determined in accordance with ASTM Method E659-78 (1994) [31]. Literature data for autoignition temperature of JP-4 are summarized in Table 4.

**Table 4:** Autoignition temperature of JP-4 and JP-5.

| Fuel     | Autoignition temperature |                    |                    | References |
|----------|--------------------------|--------------------|--------------------|------------|
|          | K                        | $^{\circ}\text{C}$ | $^{\circ}\text{F}$ |            |
| JP-4     | 524                      | 251                | 484                | [1]        |
| Kerosene | 522                      | 249                | 480                | [32]       |
| JP-5     | 518–520                  | 245–247            | 473–477            | [1]        |

### 3 Jet Fuel Kerosene JP-5

JP-5 fuel, used from 1952 to the present by the US Navy, has a 333 K (140 °F) (minimum) flash point temperature. This kerosene fuel is currently the US Navy's primary fuel and was developed mainly due to fire safety concerns aboard ships. This fuel has a freezing point temperature of 227 K (−51 °F). JP-5 does not have the anti-static additive as JP-4 and JP-8 have.

The physical properties of JP-5 and other kerosene fuels can vary considerably yet still lie within the military specification (MIL-DTL-5624W; March 2016) [1, 33]. JP-5, also known under the designation NATO F44, has been described in the Military Specification as “high flash point, kerosene type.”

#### 3.1 Physical Properties of JP-5

Physical properties of JP-5 are listed in Table 5 and reference [34].

##### 3.1.1 Density of JP-5

The military specification MIL-DTL-5624W requires that the density of JP-5 at 288 K must be in the range from 788 to 845 kg/m<sup>3</sup> = 0.788 to 0.845 g/cm<sup>3</sup> [3]. The variation of the density of numerous samples of JP-5, all within the MILSPEC limits, and their dependence on temperature, is illustrated in Figure 7. A typical sample of JP-5 had a density of 0.82 g/cm<sup>3</sup>, which is close to the average for 62 samples analyzed.

##### 3.1.2 Vapor Pressure of JP-5

The vapor pressure of JP-5 as a function of temperature is illustrated in Figure 8. The vapor pressure of a typical sample of JP-5 at 332 K was reported as 0.69 kPa (5.2 mm Hg) [3].

##### 3.1.3 Viscosity of JP-5

The kinematic viscosity of JP-5 as a function of temperature is shown in Figure 9. The military specification MIL-DTL-5624W requires that the kinematic viscosity of JP-5 at 253 K must not be higher than 7.0 mm<sup>2</sup>/s (7 cSt at −20 °C) [3].

##### 3.1.4 Surface Tension of JP-5

The surface tension of a typical sample of JP-5 at 298 K was reported to be 23.6 mN/m (23.6 dyn/cm at 25 °C) [1].

**Table 5:** Physical properties of JP-5.

| Property                                                | SI units                                                                         | Other units                                                                                 | References |
|---------------------------------------------------------|----------------------------------------------------------------------------------|---------------------------------------------------------------------------------------------|------------|
| Molecular mass for $C_{12}H_{24}$                       | 168.32 g/mol                                                                     | 5.9411 mol/kg                                                                               |            |

### 3.1.5 Thermal Conductivity of JP-5

The thermal conductivity of a typical sample of JP-5 at 298 K was reported as 0.14 W m<sup>-1</sup> K<sup>-1</sup> (0.079 BTU h<sup>-1</sup> ft<sup>-1</sup>  $^{\circ}\text{F}^{-1}$  at 77  $^{\circ}\text{F}$ ) [1].

### 3.1.6 Thermodynamic Properties of JP-5

#### 3.1.6.1 Heat Capacity of JP-5

The isobaric heat capacity  $c_p$  of JP-5 at 298 K is 1.9 J g<sup>-1</sup> K<sup>-1</sup> (0.46 BTU lb<sub>m</sub><sup>-1</sup>  $^{\circ}\text{F}^{-1}$ ).

Figure 7: Density of MIL-F-5624C (JP-5) fuel. (Reproduced and modified from [1].)

Figure 8: Vapor pressure of MIL-F-5624C (JP-5) fuel. (Reproduced and modified from [1].)

**Figure 9:** Kinematic viscosity of JP-5 as a function of temperature. (Reproduced and modified from [33].)

### 3.1.6.2 Heat of Combustion of JP-5

The heat of combustion of JP-5 varies with the source of the material. The military specification MIL-DTL-5624W requires that the net heat of combustion of JP-5 must be at least 42.6 MJ/kg (18327 BTU/lb) [3].

### 3.1.6.3 Enthalpy of Formation of JP-5

The enthalpy of formation of JP-5 varies with the source of the material and is calculated from the heat of combustion. The NASA CEA program uses an enthalpy of formation of  $-22183 \text{ J/mol}$  for a molecular mass of  $13.9448 \text{ g/mol}$  corresponding to an empirical formula of  $\text{C}_{11}\text{H}_{1.9185}$  which translates into  $\Delta H_f^{298} = -1591 \text{ J/g} = -380 \text{ cal/g}$  [5]. This number was derived from a heat of combustion of  $18600 \text{ BTU/lb}_m$ .

### 3.1.6.4 Enthalpy of Evaporation of JP-5

A graph showing the latent enthalpy of evaporation of JP-5 in comparison to that of JP-4 was already shown in Section 2.2.7.3. A similar graph has already been published (Figure 3 on page 12 of [33]).

### 3.1.7 Electrical Properties of JP-5

#### 3.1.7.1 Electric Conductivity of JP-5

The electrostatic charge buildup hazard properties of JP-5 fuel derived from alternate (non-petroleum) sources were determined [35]. Two properties, electrical conductivity and electrostatic charging tendency, were measured on seven samples. Five coal-derived fuels and one sample derived from tar sands exhibited properties similar to jet fuels derived from petroleum and hence should not develop unusual ignition hazards in field handling. A JP-5 produced from shale had higher values of conductivity and charging tendency than petroleum-derived fuels, but the combination of the two properties indicated that no abnormal electrostatic hazards should be encountered.

#### 3.1.7.2 Dielectric Constant of JP-5

The dielectric constant of JP-5 as a function of temperature is illustrated in Figure 10, based on the analysis of 62 samples, which were all within the specification limits of MIL-F-5624C [3].

**Figure 10:** Dielectric constant of JP-5 as a function of temperature. (Reproduced and modified from [1].)

### 3.1.8 Critical Point Properties of JP-5

The following critical point properties were obtained for JP-5 [36]:

$$t_{\text{crit.}} = 675 \text{ K} = 402^\circ\text{C}$$

$$P_{\text{crit.}} = 2.27 \text{ MPa} = 22.4 \text{ atm}$$

## 3.2 Chemical Properties of JP-5

### 3.2.1 Specifications for JP-5

The Military Specification for JP-5 is combined with that for JP-4. The most recent revision was MIL-DTL-5624W (March 2016) [3]. As the last letter of the specification number indicates, this specification has gone through many revisions. The specification requirements for JP-5 were already listed in Table 2 along with those of JP-4.

A maximum of 50 vol.-% of the finished fuel may consist of synthesized paraffinic kerosene (SPK) blend components derived from Fischer–Tropsch (FT)-produced SPK or hydroprocessed esters and fatty acids (HEFA). FT-SPK blend components shall conform to the requirements in ASTM D7566 Annex A1. SPK blend components derived from HEFA shall conform to requirements in ASTM D7566 Annex A2. A maximum of 10 vol.-% of the finished fuel may consist of synthesized iso-paraffins blend components derived from hydroprocessed fermented sugars.

Antioxidants are usually added to freshly processed JP-5 before the fuel is exposed to air during storage and transfer. Antioxidants are methyl-*tert*-butylphenols. The antioxidant concentration is limited to not less than 17.2mg nor more than 24.0mg of active ingredient per liter of fuel.

### 3.2.2 Thermal Decomposition of JP-5

A test program was conducted to determine the thermal stability and heat transfer characteristics of JP-5 and several other kerosene-type fuels which vary in composition and tendency to form deposits [37]. Tests were conducted over the temperature range 425 to 870 K for durations up to 32h in small-diameter, resistively heated tubes at typical aircraft engine operating conditions. A detailed mapping of the thermal decomposition characteristics of JP-5 was performed to evaluate the importance of key operating conditions such as temperature, pressure, flowrate, and test duration, and to establish a database for estimating the relative performance of new fuels in comparison to JP-5. Fuel decomposition rates varied among fuels, and the relationship between the “breakpoint temperature” (determined according to ASTM D3241) and the rate of coke deposition was investigated.

A model was developed for predicting the thermal decomposition rates of aviation fuels like JP-5 [38]. The thermal deposition model was incorporated into an existing computational fluid dynamics (CFD) code that could solve the Reynolds-averaged conservation equations of mass, momentum, and energy. The decomposition chemistry was modeled by three global Arrhenius expressions in which the fuel decomposition was assumed to be due to an autoxidation reaction with dissolved oxygen. The deposition process was modeled by assuming that all deposit-forming species transported to the wall adhered and formed a deposit. Verification of the model required the determination of the following parameters for a given fuel, in this case JP-5: (1)

the pre-exponential constant and activation energy for the wall reaction, (2) the pre-exponential constant and activation energy for the bulk autoxidation reaction, and (3) the pre-exponential constant and activation energy for the precursor decomposition reaction.

### 3.2.3 Analysis of JP-5

The list of test methods for qualification of JP-5 (or JP-4) in MIL-DTL-5624W extends over several pages. Most of those test methods are documented ASTM test methods. The list of analytical methods used for the characterization of JP-5 to verify compliance with MIL-DTL-5624W is 2½ pages long [3]. The most fundamental method used for characterization of hydrocarbon fuel blends is the distillation fraction curve, measuring the amount of distillate that has collected while the temperature in the vapor phase is rising, and also measuring the amount of less volatile residue left behind at the upper end of the distillation range.

### 3.3 Materials Compatibility with JP-5

The compatibilities of several dozen lubricants and elastomers with JP-5 were evaluated in immersion tests. Parker Fuelube, Carbowax 1500, and MIL-L-6032 lubricants are compatible with JP-5 fuel. No corrosion was promoted by contact of JP-5 fuel with metallic compounds. Teflon, fluorosilicone rubber, polyethylene, Buna N, and Kel-F elastomers are compatible with JP-5 fuel [33].

### 3.4 Toxicity of JP-5

A very detailed summary of toxicity hazards of JP-5 (as well as JP-8 and Jet A) is available from NIOSH Agency for Toxic Substances and Disease Registry, Division of Toxicology and Human Health Sciences [39]. Although JP-5 and Jet A fuels have been used for over 60 years and JP-8 was identified by the Department of Defense as its single military fuel over 30 years ago, as of 2017 there were only very little specific data on the toxicity of kerosene-based jet fuels in humans. Limited information is available on the carcinogenic potential of jet fuels in humans. Studies in laboratory animals have examined the toxicity of JP-5, JP-8, and Jet A fuels following inhalation, oral, or dermal exposure and have reported a number of targets of toxicity, including the lungs, liver, skin, immunological system, nervous system, and developing organism. Although renal effects have also been observed in male rats exposed to JP-5 or JP-8, the lesions are considered to be characteristic of  $\alpha_2\mu$ -globulin nephropathy, which is only observed in male rats and is not considered to be toxicologically relevant to hu-

mans. JP-5 was not carcinogenic in mice in a 2-year dermal bioassay. Increases in skin tumors were observed in mice dermally exposed to Jet A for 52–62 weeks; however, tumors were only observed at concentrations resulting in significant skin damage (inflammation and necrosis). Similarly, increased numbers of skin tumors were observed in mice that received applications of undiluted kerosene on the skin for 2 years, but this occurred only in the presence of moderate-to-marked skin damage. No inhalation or oral studies evaluated the carcinogenicity of JP-5, JP-8, or Jet A in laboratory animals; no increases in tumor incidences were observed in rats administered kerosene by gavage for 2 years. No human studies have examined the potential of JP-5, JP-8, or Jet A to induce respiratory effects. Studies in rats, mice, rabbits, and pigs demonstrated the dermal toxicity of topically applied JP-5, JP-8, and Jet A. Similar effects have been observed for all three fuel types.

### 3.5 Safety Properties of JP-5

#### 3.5.1 Flammability Limits of JP-5

The flammability limits of JP-5 were already listed in Table 3 along with those of JP-4. A typical JP-5 fuel has a vapor pressure of about 69 Pa (0.01 psia) at 289 K (60 °F), equivalent to a fuel : air ratio of about 0.003. This is well below the lean limit, and the tank's free space will be non-flammable provided that liquid fuel is not dispersed as a mist in this space. As is known, fuel mists in air are nearly as flammable as fuel vapors in air, and a fuel tank containing JP-5 fuel at 289 K (60 °F) can be flammable if shaken sufficiently to disperse liquid fuel droplets through the tank's free space. The temperature of JP-5 fuel must be raised to about 330 K (135 °F) before the vapor pressure becomes sufficient to exceed the lean-limit concentration.

#### 3.5.2 Flash Point of JP-5

The flash point of JP-5 determined in accordance with ASTM D56, D931, or D3828 must be above 333 K (60 °C) to meet requirements of MIL-DTL-5624W. Other sources gave a flash point of 334 K (61 °C) [6].

#### 3.5.3 Autoignition Temperature of JP-5

Data for the autoignition temperature of JP-5 were already shown in Table 4 together with the data for JP-4. The autoignition temperature of JP-5 is 497 K (435 °F) [6].

## 4 Jet Fuel Kerosene JP-7

JP-7 is a kerosene fuel with properties quite similar to those of RP-1. Its specification [40] was created to provide a fuel with high thermal stability for use in the supersonic SR-71 Blackbird. It is interesting to compare the various requirements that led to the development of various operational jet fuels, that is, comparing JP-7 to (US) Jet A (European Jet A-1), Jet Propellant JP-4 (European F-40), JP-5 (European F-44), JP-8 (F-34), JP-TS (US only), and JP-8+100 (US only) [41]. The composition of aviation fuels has generally been determined by specifications that are primarily based upon operational requirements. These include heat content, fluidity, corrosion protection, and stability. Successful demonstration of hydrocarbon-fueled hypersonic technology was achieved with a flight test of an X-51A Waverider vehicle burning JP-7, but JP-7 is no longer in production [42].

Although JP-7 also meets the operational demands for hypersonic aircraft (Mach 5+), this fluid is no longer produced. There was a proposal in the hypersonic vehicle community to replace JP-7 with the rocket propellant RP-2; however, research and testing was necessary to determine whether this substitution would be possible [43]. The advanced distillation curve method was applied to a representative sample of the hypersonic vehicle fuel JP-7 in comparison to RP-2.

### 4.1 Physical Properties of JP-7

Properties of JP-7 are summarized in reference [44].

#### 4.1.1 Freezing (Melting) Point of JP-7

The maximum allowed freezing (melting) point of JP-7 specified per MIL-DTL-38219D is 229.8 K ( $-43.3^{\circ}\text{C}$ ) [40]. A typical freezing point of JP-7 is 229 K ( $-44^{\circ}\text{C} = -47.5^{\circ}\text{F}$ ).

#### 4.1.2 Boiling Range of JP-7

The boiling range of JP-7 per MIL-DTL-38219D is 455–561 K ( $182\text{--}288^{\circ}\text{C} = 360\text{--}550^{\circ}\text{F}$ ) [40].

#### 4.1.3 Density of JP-7

The density of JP-7 at 288 K ( $15^{\circ}\text{C}$ ) specified per MIL-DTL-38219D is  $0.779\text{--}0.806\text{ g/cm}^3$  [40].

#### 4.1.4 Vapor Pressure of JP-7

The minimum required vapor pressure of JP-7 per MIL-DTL-38219D is 20.7 kPa at 422 K (149 °C) and 331 kPa at 533 K (260 °C) [40]. A typical measured vapor pressure of JP-7 was 0.048 kPa at 298 K (0.36 mm Hg at 25 °C).

#### 4.1.5 Viscosity of JP-7

The maximum allowed kinematic viscosity of JP-7 at 253 K (−20 °C) per MIL-DTL-38219D is 8.0 mm<sup>2</sup>/s (8 cSt). Typical kinematic viscosity of JP-7 is about 1.775 mm<sup>2</sup>/s at 298 K (1.775 cSt at 25 °C).

#### 4.1.6 Surface Tension of JP-7

The surface tension of a sample of JP-7 was measured as 0.002255 mN/m at 298 K (0.002255 dyn/cm at 25 °C) [44].

#### 4.1.7 Heat Transfer Coefficient of JP-7

Heat transfer and flow instabilities in supercritical fuels in vertical tubes with upward flow were studied with JP-7 or methylcyclohexane as the test fluids with heat fluxes of 250 kW/m<sup>2</sup> and nominally turbulent ( $N_{Re} \sim 30000$ ) conditions [45]. At times, complete flow reversals with pressure amplitudes of 540 kPa (80 psid) and fluid exit temperature fluctuations of 100 °C were observed.

A series of electrically heated tube experiments was conducted to investigate the potential of JP-7 as a coolant under aerodynamic heating conditions of a Mach 8 scramjet propulsion system [46, 47]. The heat transfer capabilities, carbon deposition, and material compatibility of JP-7 at surface temperatures up to 1200 K (927 °C) were tested in 3.17-mm (0.125-in.) diameter tubes of 304 SS, Inconel 617, Haynes 188, Haynes 230, and 50150 moly-rhenium. The heat transfer to the coolant was modeled well by a Dittus-Boelter correlation at lower heat fluxes. At higher heat fluxes, audible instabilities were observed and corresponded to a significant enhancement in the coolant heat transfer rates. The carbon deposition rates in these tests were comparable to those in previous experiments at lower heat fluxes and much longer residence times. This result suggested that alternative paths of the deposition mechanism may be enhanced under high heat flux test conditions. Microscopic investigation of the test tubes after the experiments indicated that there was a significant layer of ordered carbon deposits that had not been seen in the tests at lower heat flux.

#### 4.1.8 Thermodynamic Properties of JP-7

##### 4.1.8.1 Heat Capacity of JP-7

The heat capacity of JP-7 is  $c_p = 2.025 \text{ J g}^{-1} \text{ K}^{-1}$  at 298 K ( $0.484 \text{ cal g}^{-1} \text{ }^\circ\text{C}^{-1}$  at  $25^\circ\text{C}$ ) [44].

##### 4.1.8.2 Enthalpy of Formation of JP-7

The enthalpy of formation of liquid JP-7 is  $\Delta H_f^{298} = -1799 \text{ J/g} = -430 \text{ cal/g}$  calculated from the heat of combustion [48].

##### 4.1.8.3 Heat of Combustion of JP-7

The minimum net heat of combustion of JP-7 per MIL-DTL-38219D is  $43.5 \text{ MJ/kg} = 18700 \text{ BTU/lb}$  [40]. The volumetric net heat of combustion of JP-7 is  $34000 \text{ MJ/m}^3 = 124600 \text{ BTU/gal}$ .

##### 4.1.8.4 Enthalpy of Evaporation of JP-7

Assuming that the gross formula of JP-7 is  $\text{C}_{12}\text{H}_{25}$  and using correlation gas chromatography (GC) and nuclear magnetic resonance (NMR) spectrometry, the vaporization enthalpy of JP-7 was predicted to be  $341 \text{ kJ/kg}$  [49].

#### 4.1.9 Critical Point Properties of JP-7

The critical point properties of JP-7 were measured and calculated. A critical temperature of  $678 \text{ K}$  ( $761^\circ\text{F}$ ) was measured and a critical temperature of  $673 \text{ K}$  ( $751^\circ\text{F}$ ) and critical pressure of  $2.10 \text{ MPa}$  ( $305 \text{ psia}$ ) was calculated from boiling range data and density. The critical density is  $0.792 \text{ g/cm}^3$  at  $298 \text{ K}$  ( $49.5 \text{ lb}_\text{m}/\text{ft}^3 = 6.62 \text{ lb}_\text{m}/\text{gal}$  at  $77^\circ\text{F}$ ).

#### 4.2 Chemical Properties of JP-7

The empirical gross formulas for JP-7 cover a wide range of compositions. The proposed formulas are  $\text{C}_{12.5}\text{H}_{26}$ ,  $\text{C}_{12.1}\text{H}_{24.4}$ ,  $\text{C}_{12.3}\text{H}_{25.5}$ , and  $\text{C}_{15.1}\text{H}_{32.7}$ . The molecular mass is different for each of these formulas. One must not report thermophysical properties in terms of property per mol without specifying the average molecular mass this property was calculated for. JP-7 is a hydrocarbon-based kerosene fraction with a low volatility and high thermal stability. JP-7 was developed in the 1950s to meet the more stringent requirements necessary for the development of high-altitude reconnaissance aircraft that fly at speeds exceeding Mach 3. The extreme temperatures encountered due to the heat transmitted from compressed air on the aircraft, and air resistance, required the development of fuels with improved thermal stability and higher flash points. Although JP-7 also meets the operational demands for hypersonic aircraft (Mach 5+), this fluid is no longer produced. There may still be a desire in the hypersonic vehicle community to replace JP-7 with the rocket propellant RP-2. However, research and testing

would be necessary to determine whether this substitution will be possible. The advanced distillation curve method was used to characterize a representative sample of the hypersonic vehicle fuel JP-7 [43]. Specifically, the thermodynamically consistent distillation curve and the composition channel were used to characterize the curve in terms of composition and available energy content. The results were compared with previous measurements performed on the rocket propellants RP-1 and RP-2 to provide a basis of comparison among these fuels in terms of the fundamental thermophysical properties.

#### 4.2.1 Specifications for JP-7

JP-7 was a fuel created from special blending stocks to create a fuel with low vapor pressure, high thermal oxidation stability, and low volatility. It was developed for the SR-71 Blackbird in the 1960s but is no longer used. The specification requirements (chemical composition, physical properties, test methods) for JP-7 per MIL-DTL-38219D [40] are listed in Table 6.

JP-6 per MIL-J-2565 was a kerosene-based fuel developed in 1956 for the XB-70 Valkyrie aircraft. JP-6 was intended for the high altitude bomber, being similar to JP-5 but with a lower freezing point and improved thermal oxidative stability. When the XB-70 program was cancelled, the JP-6 specification, MIL-J-25656, was also cancelled.

#### 4.2.2 Composition of JP-7

To prevent the formation of gums and peroxides, one of the following antioxidants shall be blended into the fuel immediately after it is processed and before it is exposed to air. The antioxidant shall be added to the fuel at a concentration of 24 mg of inhibitor (not including weight of the solvent) per liter of fuel:

- a. 2,6-di-*tert*-butyl-4-methylphenol
- b. 2,4dimethyl-6-*tert*-butylphenol
- c. 2,6-di-*tert*-butylphenol
- d. Mixed *tert*-butylphenol composition:
  - 75% 2,6-di-*tert*-butylphenol
  - 10–15% 2,4,6-tri-*tert*-butylphenol
  - 10–15% *ortho-tert*-butylphenol

#### 4.2.3 Analysis of JP-7

Analysis methods for JP-7 are described in the MIL SPEC MIL-DTL-38219D [40].

**Table 6:** JP-7 chemical and physical requirements and test methods per MIL-DTL-38219D.

| Requirements                                                    | Minimum           | Maximum               | ASTM Standards test methods  |
|-----------------------------------------------------------------|-------------------|-----------------------|------------------------------|
| Aromatics, vol.-%                                               |                   | 5                     | D1319                        |

<sup>a</sup> The mercaptan determination may be waived at the option of the inspector if fuel is “Doctor Sweet” when tested in accordance with ASTM D4952.

<sup>b</sup> A condenser temperature of 0 to 4.4 °C (32 to 40 °F) shall be used. To insure accurate IBP data, the operator must cut back on the heating rate when the vapor/condensate ring rises to within about 25 mm (1 in.) of the vapor tube. The reduced heating rate allows the thermometer to more accurately reflect the true vapor temperature when the first condensate is collected.

<sup>c</sup> The temperature reading at the 20 percent recovered point shall be corrected for the emergent stem in accordance with ASTM E77, paragraph 7, Treatment of Data.

<sup>d</sup> Test shall be performed in accordance with the vapor pressure test in Appendix A or Appendix C of this specification.

<sup>e</sup> Until an ASTM thermometer calibrated for the −20 °C condition becomes available, this test may be conducted at −34.5 °C (−30 °F) with a maximum allowable viscosity of 15.0 centistokes

#### 4.2.4 Thermal Stability of JP-7

Experimental studies have shown that trace amounts of fuel-soluble metal compounds can be very detrimental to the thermal stability of JP-7. Adverse effects on fuel thermal stability have been demonstrated by gas-driven fuel coker tests on JP-7 fuels containing as little as 15 to 25 parts per billion of added iron or copper, or 100 to 250 parts per billion of added zinc or lead [50]. The true threshold concentrations were generally lower, since the added metal tended to disappear from fuel samples during storage and handling. The ambiguities in metal content hinder any clear correlation and make it impractical to recommend metal-content limits for fuel quality control.

Thermal cracking of JP-7 flowing through a heated tube was investigated as a possible high temperature heat sink for supersonic aircraft [51]. It was found that the endothermicity of the reactions was on the order of 697 kJ/kg (300 BTU/lb), much less than the theoretical maximum of 3487 kJ/kg (1500 BTU/lb). The decrease from the theoretical value was due to significant formation of saturated species and aromatics. The endothermic heat of reaction peaks at 40–60% conversion for both pure hydrocarbons and hydrocarbon fuel mixtures. The heat of reaction ranges from 323–930 kJ/kg (100–400 BTU/lb) of fuel converted. This heat of reaction is much smaller than the maximum calculated by assuming 100% ethylene formation 3487 kJ/kg (1500 BTU/lb). Increasing conversion above 60% leads to decreased reaction endothermicity due to increased formation of saturated products. Pressure had little effect between 1.38 and 6.89 MPa (200 and 1000 psig).

#### 4.3 Toxicity of JP-7

A very detailed toxicological profile of JP-7 was published which also included toxicity data for JP-4 [26].

#### 4.4 Safety Properties of JP-7

##### 4.4.1 Flash Point of JP-7

The flash point of JP-7 is 333 K (60 °C = 140 °F).

##### 4.4.2 Autoignition Temperature of JP-7

The autoignition temperature of JP-7 in air is 514 K (241 °C = 465 °F). Electrostatic discharges with a spark energy of 0.2 mJ are sufficient to ignite JP-7 vapors in air.

##### 4.4.3 Flammable Range of JP-7 Vapors

The flammable range of JP-7 vapors in air is from 0.6 to 4.6 vol.-%.

## 5 Jet Fuel Kerosene JP-8

JP-8 was first introduced at NATO bases in 1978 and is currently the US Air Force's primary fuel. JP-8 is very similar to Jet A-1. JP-8, however, contains an icing inhibitor, corrosion/lubricity enhancer, and anti-static additive. Conversion to JP-8 was virtually complete in 1995 and was accomplished for fire safety and combat survivability reasons.

JP-8 (MIL-DTL-83133E, NATO code F-34) is the current US Air Force fuel for essentially all aircraft and ground vehicles [52]. As the "single fuel for the battlefield," the US Army plans to transition to a single fuel, JP-8, for all ground vehicles and aircraft. US Navy aircraft typically fly on JP-8 from land bases, but use a higher flash point fuel (JP-5) when based on carriers.

JP-8 is essentially commercial kerosene Jet A/Jet A-1 fuel with three military-specified additives: a corrosion inhibitor/lubricity improver, an anti-static additive, and a fuel system icing inhibitor. JP-8 replaced JP-4 in general Air Force use in the 1980s, primarily to reduce the risk of fire encountered with the low-flash-point JP-4. JP-TS and JP-7 are specialty fuels used for the U-2 and SR-71, respectively.

In 1979, USAF operations within the United Kingdom were converted from JP-4 (NATO designation F-40) to JP-8 (NATO F-34). NATO and USAF operations in Europe converted to JP-8 by the end of 1988. Gradually all USAF operations in the Pacific (Japan, Korea, and Okinawa) converted to JP-8 by 1991. Eventually USAF also converted continental US (CONUS) operations to JP-8. Although not widely used within the CONUS, Jet A-1 is the primary commercial jet fuel for the rest of the free world. In NATO, much of the JP-8 will be procured and shipped as Jet A-1, with the special additives, required to convert the Jet A-1 into JP-8, injected into the fuel prior to its delivery to air bases [53]. A synthetic fuel with JP-8 properties was made by the Fischer-Tropsch process and was compared to JP-8 made from petroleum [54].

### 5.1 Physical Properties of JP-8

The physical properties of JP-8 are listed in Table 7. Models were developed to represent the thermophysical properties of aviation kerosenes described under the umbrella names of Jet A and JP-8 [54, 55]. Measurements included the chemical analysis of finished fuels, studies of the thermal decomposition of fuels and components, measurement of the volatility, density, velocity of sound, viscosity, and thermal conductivity of finished fuels and their selected components. The modeling efforts included the development of equations of state for a suite of potential surrogate components, and the development of models based on the Helmholtz free energy equation of state. A GC-MS analysis of a typical sample of JP-8 showed about 50 peaks in the fractogram, most of which could be identified by MS. Properties of pure methylcyclohexane and

**Table 7:** Physical properties of JP-8.

propylcyclohexane were measured so they could be used as constituents of surrogate fuel mixtures.

Additive packages are used with aviation kerosenes to achieve performance enhancements, such as higher or lower operating temperatures or increased lubricity. An additive that is used to increase operating temperatures for heat sink applications is the +100 additive that is added to JP-8. As part of an effort to characterize JP-8, the effect of the +100 additive on the volatility of JP-8 was measured by using the composition-explicit or advanced distillation curve approach [56]. It was found that the vaporization temperatures increased modestly in the early stages of the distillation but the difference disappeared after the 70% distillate fraction. Selected components of the additive were tracked through the distillation curve and related the concentration to the temperature data grid. This allowed the determination of the heaviest components of the additive which were concentrated late in the distillation curve and a significant quantity in the recovered residue.

### 5.1.1 Density of JP-8

The density range of JP-8 specified by MIL-DTL-83133J is 0.775–0.840 g/cm<sup>3</sup> at 288 K (15 °C).

### 5.1.2 Viscosity of JP-8

Per MIL-DTL-83133J, the maximum allowed kinematic viscosity of JP-8 at 253 K ( $-20^{\circ}\text{C}$ ) is  $8.0\text{ mm}^2/\text{s}$  (8 cSt). The kinematic viscosity of JP-8 was measured in the range 300–547 K and at pressures up to 50 MPa [54]. The kinematic viscosity of JP-8 as a function of temperature is shown in Figure 11. Similar data are available for a synthetic JP-8 type fuel with a designation of S-8 made by the Fischer–Tropsch process.

**Figure 11:** Kinematic viscosity of JP-8 as a function of temperature. (Reproduced and modified from [54].)

### 5.1.3 Surface Tension of JP-8

The surface tension of JP-8 at 300 K was reported as  $25.85\text{ mN/m} = 25.85\text{ dyn/cm}$  [4].

### 5.1.4 Thermal Conductivity of JP-8

The thermal conductivity of JP-8 was measured over a range from 300 to 547 K at pressures up to 50 MPa [54]. The thermal conductivity of JP-8 at 300.7 K and a pressure of 0.781 MPa was  $0.1157\text{ W m}^{-1}\text{ K}^{-1}$ . The thermal diffusivity of JP-8 at 298 K is  $8.7 \times 10^{-8}\text{ m}^2/\text{s}$ .

### 5.1.5 Thermodynamic Properties of JP-8

#### 5.1.5.1 Heat Capacity of JP-8

The heat capacity of JP-8 can be calculated from the least-squares generated equation for the heat capacity at ambient pressure [54]:

$$C_p/C_p^0 = (2.193 \pm 0.0055) + (3.996 \pm 0.0011) \times 10^{-3} (T/T_0 - 1)$$

where  $C_p/C_p^0$  is the ratio of heat capacities at temperature  $T$  in relation to the heat capacity at a reference temperature  $T_0$  (in kelvin).

#### 5.1.5.2 Heat of Combustion of JP-8

The minimum lower (net) heat of combustion of JP-8 as specified by MIL-DTL-83133J is 42.8 MJ/kg (18413 BTU/lb).

#### 5.1.5.3 Enthalpy of Evaporation of JP-8

Assuming that the gross chemical formula of JP-8 is  $C_{11}H_{21}$ , and using correlation GC and NMR, the evaporation enthalpy of JP-8 was predicted to be 441 kJ/kg [49].

### 5.1.6 Critical Point Properties of JP-8

The critical temperatures of some petroleum- and coal-derived jet fuels were measured using a rapid heating sealed tube method [57]. A critical property estimation method was used to calculate the critical temperatures and pressures of the jet fuel samples. Five other methods were also used to estimate the critical temperatures of these fuels. While most of the estimation methods gave satisfactory predictions of the critical temperatures of the petroleum-derived jet fuels, they were not able to predict the results for the coal-derived jet fuels. The larger differences between the measured and estimated critical temperatures for the coal-derived fuels were attributed to the different composition of these fuels, dominated by cycloalkanes. On the basis of properties of the compounds found in the coal-derived jet fuels, a new correlation was proposed to calculate the critical temperatures of the coal-derived jet fuels. Six petroleum-derived jet fuels (designated as JP-8P, JP-8P2, Jet A, Jet A-1, JP-7, and JPTS) and three coal-derived jet fuels (JP-8C, JP-8CA, and JP-8CB) were used. The petroleum-derived jet fuels were composed mainly of long-chain paraffins, while JP-8C consisted mainly of monocyclic and bicyclic alkanes and some two-ring hydroaromatic compounds. The compositions of JP-8CA and JP-8CB were similar to that of JP-8C, although JP-8CA contained higher concentrations of low-boiling-point compounds, while JP-8CB was richer in high-boiling-point compounds. A sealed tube method was used to measure the critical temperatures of the jet fuels. This method consisted of sealing a certain amount of sample in a glass tube with a volume which was approximately equal to the critical volume of the sample at the critical temperature and then heating it rapidly in a furnace until the critical point was reached. The critical temperature of JP-8 is 666–684 K (740–772 °F) and the critical pressure is 2.344 MPa (340 psia).

## 5.2 Chemical Properties of JP-8

### 5.2.1 Specifications for JP-8

The properties of JP-8 are specified in MIL-DTL-83133J, Detail Specification: Turbine Fuel, Aviation, Kerosene Type, JP-8 (NATO F-34), NATO F-35, and JP-8+100 (NATO F-37) (16 December 2015) (Table 8). This specification covers three grades of kerosene type aviation turbine fuel: JP-8 (NATO F-34), NATO F-35, and JP-8+100 (NATO F-37).

**Table 8:** JP-8 Chemical and physical requirements and test methods per MIL-DTL-83133J.

| Tube rating: One of the following requirements shall be met:       |       |                   |                                                                         |
| (1) Annex A1 VTR or                                                | <3    |                   |                                                                         |
| (2) Annex A3 ETR or Annex A2 ITR                                   |       |                   |                                                                         |
| average deposit thickness, nm, over<br>area of 2.5 mm <sup>2</sup> | 85    |                   |                                                                         |

**Table 8:** (continued)

| Property                                        | Min. | Max. | ASTM or IP test method      |
|-------------------------------------------------|------|------|-----------------------------|
| Fuel system icing inhibitor, vol.-%             | 0.07 | 0.10 | D5006                       |
| Fuel electrical conductivity, pS/m <sup>e</sup> |      |      | D2624                       |
| Existent gum, mg/100 mL                         |      | 7    | D381 <sup>b</sup> or IP 540 |
| Water reaction interface rating                 |      | 1b   | D1094                       |
| Microseparometer rating                         |      |      | D3948 or D7224 <sup>b</sup> |

<sup>a</sup> To be reported – not limited.

<sup>b</sup> Referee Test Method.

<sup>c</sup> The sulfur content detection range for ASTM D3120 is 3.0 to 1000 mg/kg.

<sup>d</sup> If the Doctor Test results in a failure ('positive' result), then mercaptan sulfur content shall be determined by the referee test method ASTM D3227.

<sup>e</sup> The conductivity must be between 150 and 600 pS/m for JP-8 (NATO F-34) and between 50 and 600 pS/m for NATO F-35, at ambient temperature or 29.4 °C (85 °F), whichever is lower, unless otherwise directed by the procuring activity. In the case of JP-8+100 (NATO F-37), JP-8 with the thermal stability improver additive (see Section 3.3.6 of MIL-DTL-83133), the conductivity limit must be between 150 and 700 pS/m at ambient temperature or 29.4 °C (85 °F), whichever is lower, unless otherwise directed by the procuring activity.

Conventional petroleum-derived jet fuel is the most broadly specified fuel. The density range for JP-8 (and Jet A as specified in ASTM D165515) is greater than that of RP-1 by a factor of four. JP-8 specification properties are measured for each batch procured by the Defense Energy Support Center (DESC) and published annually in the Petroleum Quality Information System (PQIS). The report summarizes procurement quantities and specification properties for several product grades and includes statistics (historical trends, geographical region, number of analyses, minimum, maximum, mean, and weighted mean values) useful for assessing fuel variability. The only hydrocarbon composition quantity measured is total aromatic compounds, which for JP-8 was at a weighted mean of 17.92 vol.-% in 2008 [58]. Describing fuel composition by hydrocarbon type distribution is a practical approach for comparing complex kerosenes, particularly since performance is often related to compound classes rather than particular species. The introduction of hydrocarbon class requirements in fuel specifications (cycloparaffin content is limited to 15% by volume for Fischer–Tropsch synthetic paraffinic kerosene blend stocks in jet fuel) leads to increased relevance of compositional descriptions via compound type. The 2006 World Fuel Sampling Program collected 54 fuel samples (JP-8, Jet A, Jet A-1) worldwide, compiling numerous property and performance data which included fuel compositional analysis by hydrocarbon class according to ASTM D2425.

### 5.2.2 Composition of JP-8

The average composition and minimum and maximum property numbers observed in delivered JP-8 and Jet A accumulated during a decade of observation were compared to the specification limits for JP-8 [53]. For comparison, the study also included the average properties of Jet A fuels prior to the addition of the additives.

#### 5.2.2.1 Antioxidants

Immediately after processing and before the fuel is exposed to the atmosphere (such as during rundown into feed/batch tankage), an approved antioxidant formulation or combination of approved antioxidant formulations are added in order to prevent the formation of gums and peroxides after manufacture. The concentration of antioxidant to be added shall be:

- a. Not less than 17.2 milligrams (mg) nor more than 24.0 mg of active ingredient per liter (L) of fuel to all JP-8 fuel that contains blending stocks that have been hydrogen treated or SPK derived from hydrotreated, hydrocracked, or hydroisomerized products of a Fischer–Tropsch or HEFA process.
- b. At the option of the supplier, not more than 24.0 mg of active ingredient per liter of fuel may be added to JP-8 fuels that do not contain hydrogen-treated blending stocks or SPK-derived from hydrotreated, hydrocracked, or hydroisomerized products of a Fischer–Tropsch or HEFA process.

#### 5.2.2.2 Antioxidant Formulations

The following antioxidant formulations are approved:

- 2,6-di-*tert*-butyl-4-methylphenol
- 6-*tert*-butyl-2,4-dimethylphenol
- 2,6-di-*tert*-butylphenol
- 75% min. 2,6-di-*tert*-butylphenol, 25% max. *tert*-butylphenols and tri-*tert*-butylphenols
- 72% min. 6-*tert*-butyl-2,4-dimethylphenol, 28% max. *tert*-butyl-methylphenols and *tert*-butyl-dimethylphenols
- 55% min. 2,4dimethyl-6-*tert*-butylphenol and 15% min. 2,6-di-*tert*-butyl-4-methylphenol and 30% max. mixed methyl and dimethyl *tert*-butylphenols

JP8+100 contains dispersants (surface active agents with fuel soluble tail), antioxidants (2,6-di-*tert*-4-methylphenol), and metal deactivators which function by forming a chelate with the metal.

### 5.2.3 Surrogate Fuel Mixtures for JP-8

Because of the complexities involved in measuring and modeling the performance and properties of finished fuels, the fuel science community must often use surrogate mixtures as substitutes, especially in the absence of consensus standard mixtures. While surrogate mixtures are often formulated on the basis of the ability of a particular mixture to reproduce a particular property, there is usually a desire to employ surrogate mixtures that are physicochemically authentic. This means that, provided that the primary purpose is satisfied, researchers are inclined to choose mixtures that have physical and chemical properties appropriate to the finished fuel.

Jet A and JP-8 consist of complex mixtures of higher order hydrocarbons, including alkanes, cycloalkanes, and aromatic molecules. Surrogate mixtures were needed to represent JP-8 fuels and to discuss a general detailed chemical kinetic model for jet fuels. A surrogate blend of six pure hydrocarbons was found to adequately simulate the distillation and compositional characteristics of a practical JP-8 [59]. A hierarchically constructed kinetic model already available for the oxidation of alkanes and simple aromatic molecules (benzene, toluene, ethylbenzene, xylene, etc.) was extended to include methylcyclohexane and tetralin as new reference fuel components. The kinetic model was validated through comparisons with experimental data for the pure components and it was also used to verify and predict the structures of laminar premixed flames of different pure components as well as conventional kerosene fuels.

Surrogate fuel mixtures were developed for a synthetic fuel meeting JP-8 criteria made from coal by the Fischer–Tropsch process [60]. The properties of the surrogate model were then compared with experimental density, sound speed, viscosity, thermal conductivity, and distillation curve data for the real fuel.

Experimental and numerical studies were carried out to develop a surrogate that can reproduce selected aspects of combustion of kerosene jet fuels, in particular Jet A1, Jet A, and JP-8 [61]. Surrogate fuels are defined as mixtures of few hydrocarbon compounds with combustion characteristics similar to those of commercial fuels. A mixture of 80 mass-% *n*-decane and 20 mass-% 1,2,4-trimethylbenzene, called the Aachen surrogate, was selected for consideration as a possible surrogate of kerosene. Combustion experiments were carried out employing a counterflow configuration. The fuels tested were real kerosene and the Aachen surrogate. Critical conditions of extinction, autoignition, and volume fraction of soot measured in laminar non-premixed flows burning the Aachen surrogate were found to be similar to those in flames burning kerosene. A chemical kinetic mechanism was developed to describe the combustion of the Aachen surrogate. This mechanism was assembled using previously developed chemical kinetic mechanisms for the components: *n*-decane and 1,2,4-trimethylbenzene. The combined mechanisms were validated using experimental data obtained from shock tubes, rapid compression machines, jet stirred reactor, burner-stabilized premixed flames, and a freely propagating premixed flame. Numerical calculations were performed using the chemical kinetic

mechanism for the Aachen surrogate. The calculated values of the critical conditions of autoignition and soot volume fraction agreed well with experimental data.

#### 5.2.4 Analysis of JP-8

The analytical methods used to verify compliance of JP-8 with the requirements of MIL-DTL-83133J are spelled out in MIL-DTL-83133J.

- a. Acid Number. The acid number controls the amount of acidic components in the fuel, carried over from the crude oil, formed or added in refinery processes, or added after processing. The specification level is 0.015 mg KOH/g fuel.
- b. Aromatics Content. Aromatics are unsaturated, cyclic hydrocarbons that are excellent solvents, have a strong odor (hence the name aromatics), and have poor combustion performance. As the solvency of aromatics causes some elastomers to swell excessively, specifications typically limit aromatics content to 20 to 25 vol.-%. The poor combustion performance of aromatics is another reason for limiting aromatics content of jet fuels. None of the JP-8 fuels tested during a field survey exceeded or even closely approached the specification limit of 25% aromatics [53]. The average aromatics content of JP-8 was slightly less than that for Jet A (16.4 vs. 17.8 vol.-%.)
- c. Olefins Content. Olefins are chain and branched chain paraffins that have double carbon bonds. As the double carbon bonds cause olefins to be less stable, olefins are limited to 5 vol.-%. Average olefins content of JP-8 and Jet A during a field study was 1.0 and 1.2 vol.-%, respectively. However, the accuracy of the test method used to measure olefins content is poor, so the differences in the average values is meaningless. As the most likely source of olefins is cracked petroleum stocks, the specification limit on olefins effectively limits the use of thermally and catalytically cracked stocks.
- d. Sulfur Content. Sulfur is limited in jet fuels because of its corrosivity and the noxious nature of its combustion products. The specification limit for JP-8 and Jet A is 0.3 mass-%. During a field study, both JP-8 and Jet A had average sulfur contents well below specification limits, but JP-8 averaged 0.08 vs. 0.05 mass-% for Jet A.
- e. Mercaptan Sulfur Content. Mercaptan sulfur is one of the most noxious forms of sulfur, both in odor and in corrosiveness. During a field survey, none of the JP-8 fuels exceeded the specification limit of 0.002 mass-%, and the average mercaptan sulfur content of JP-8 was only slightly less than that for Jet A, which has a specification limit of 0.003 mass-%.
- f. Distillation Range. The distillation ranges for JP-8 and Jet A are identical. None of the JP-8 fuels tested approached either the maximum allowable 10% recovered temperature or the end point temperature.
- g. Flash Point. The average flash point for Jet A was significantly higher than for JP-8. This correlated with the higher average distillation temperatures of Jet A.

- h. Gravity. All JP-8 fuels met the gravity limits. As API gravity is inversely related to specific gravity, the higher average API gravity for JP-8, as compared to Jet A, meant that JP-8 was less dense than Jet A. The higher density of Jet A correlated with the higher distillation range and aromatics content of Jet A.
- i. Freezing Point. Aside from additives, the major difference between JP-8/Jet A-1 and Jet A is the freezing point requirement. All JP-8 fuels tested had freezing points of 226 K ( $-47^{\circ}\text{C}$ ) or below. With a maximum allowable freezing point of 233 K ( $-40^{\circ}\text{C}$ ), the average Jet A freezing point was 228 K ( $-45^{\circ}\text{C}$ ).
- j. Viscosity. Engine starting and altitude relight performance requires excellent fuel atomization, and atomization is a function of viscosity. Although the viscosity limit for JP-8, Jet A-1, and Jet A is the same, viscosity tends to correlate with freezing point, density, and distillation range. The average viscosity of numerous samples of JP-8 collected in a field survey was less than for Jet A [53].
- k. Smoke Point. The smoke point is the maximum flame height (in millimeters) that can be obtained without smoking, using a standard wick lamp. Smoke point correlates with fuel combustion performance in gas turbine engines. A high smoke point insures that the fuel will burn with a minimum of exhaust smoke and minimum heat transferred to the combustor liner via radiation.
- l. Hydrogen Content. The hydrogen content of jet fuels correlates with fuel combustion performance. For the JP-8 fuels the mass percent hydrogen is calculated using ASTM D 3343. During a 1988 field survey, all JP-8 fuels met or exceeded the minimum allowable hydrogen content of 13.4 % required by specification MIL-T-83133B.
- m. Heat of Combustion. The calorific value of a fuel can be measured directly in a calorimeter or estimated using correlations based on other fuel measurements. During a 1988 field survey, all but one JP-8 met or exceeded the minimum specification limit of 42798 kJ/kg (18400 BTU/lb). The JP-8 fuels had a slightly higher heat of combustion than Jet A fuels.
- n. Thermal Oxidative Stability. Jet fuel is the primary coolant for airframe, engine components, and engine lubricant. As aircraft become more complex and engine fuel flow rates decrease with increasing engine efficiencies, fuel temperatures increase. Fuel must withstand these higher temperatures without forming deposits within the fuel system. A jet fuel thermal oxidative tester (JFTOT) test apparatus is used to insure that each batch of fuel has acceptable stability. The JFTOT monitors the formation of deposits on a heated, polished aluminum tube and plugging of a filter downstream of the heated tube. The tube deposit must be less than code 3 (a dark tan) and the pressure drop across the filter must not exceed 25 mm of mercury.
- o. Existent Gum. Jet fuels are good solvents and may contain quantities of dissolved polymeric gums and resins, which can form deposits within the fuel system and combustor. To analyze for existent gum, a sample of the fuel is evaporated and the remaining residue is weighed.

- p. **Particulate Matter.** This test measures the quantity of solid particulates by filtering 3.78 L (1 gallon) of fuel through a 0.8-micron pore size filter membrane, which is weighed before and after the filtration.
- q. **Filtration Time.** Department of Defense (DoD) jet fuel specifications limit the time required to filter 3.78 L (1 gallon) of jet fuel through a 0.8-micron filter. This test is run in conjunction with the particulate matter test. The purpose of this test is to insure that the fuel does not contain contaminants that will rapidly plug the filters and filter-water separators in the bulk fuel storage and servicing systems at Air Force bases. The contaminants that can plug filters include solid particulates (sand, rust, fibers, etc.), precipitates from refinery treating solutions left in fuels, and reaction products of fuel corrosion inhibitors (fatty acids that have reacted with water and metals to form gelatinous soap-like materials).
- r. **Water Separation Index.** The most common and potentially serious contaminant in jet fuel is water. Filter-water coalescer/separator devices are used in the base fuel servicing systems to remove particulates and undissolved water. The water is removed by coalescence, i.e., small water droplets coalesce to form large droplets that are then separated by gravity and hydrophobic filter media. However, coalescence of water can be degraded or prevented by trace quantities of surface active (surfactants, emulsifiers) materials in the fuel. The water separation index (modified) apparatus consists of a miniature coalescer device through which a sample of the fuel, emulsified with water, is passed. The ability of the coalescer to remove the water is then determined. A water separation index modified (WSIM) rating of 100 is excellent; a rating of less than 70 is cause for concern. As fuel additives affect the WSIM, different limits are placed on the fuel, depending on which additives are present. With corrosion inhibitor (CI) but not the static dissipator additive present, a minimum WSIM of 70 is allowed. The presence of the corrosion inhibitor does significantly lower the WSIM. The average WSIM value of 95 for the Jet A fuels (which normally do not contain corrosion inhibitor additives) is essentially the same as for the JP-8 fuels that do not contain a corrosion inhibitor additive.
- s. **Fuel Additives.** JP-8 requires, as mandatory additives, fuel system icing inhibitor, corrosion inhibitor/lubricity improver, and static dissipator additives, and their concentrations need to be monitored. Antioxidants are optional unless the fuel has been hydrogen treated, in which case the antioxidant is also mandatory. The metal deactivator additive is optional.

Several improvements in the measurement of distillation curves for complex fluids were introduced [62]. The modifications to the classical measurement provided for (1) a composition explicit data channel for each distillate fraction (for both qualitative and quantitative analysis); (2) temperature measurements that are true thermodynamic state points; (3) temperature, volume, and pressure measurements of low uncertainty suitable for an equation of state development; (4) consistency with a century of historical data; (5) an assessment of the energy content of each distillate fraction; (6)

a trace chemical analysis of each distillate fraction; and (7) a corrosivity assessment of each distillate fraction. The most significant modification was achieved with a new sampling approach that allowed precise qualitative as well as quantitative analyses of each fraction, on the fly. The new method was applied to the measurement of rocket propellant, military aviation fuel JP-8, and also to a coal-derived fuel developed as a potential substitute. Each fraction of the distillation was chemically characterized.

### 5.2.5 Thermal Stability of JP-8

The object of a research program was to determine which components of an oxidized fuel are most responsible for deposits on hot engine parts [63]. A 5° boiling range cut of a JP-8 fuel was oxidized with air at 373 K (100 °C) and then fractionally distilled (separated) at 25 and 5 mm Hg pressure into (essentially) recovered fuel, a high-boiling fraction (containing monomeric oxidation products), and a residue (containing bi-functional and polymeric materials). Restoration of polymeric oxidation products to the original or recovered fuels greatly increased deposit formation in the jet fuel thermal oxidation tester (JFTOT) per ASTM D 3241, but restoration of monomeric oxidation products had little effect.

JP-8 was not initially formulated to serve as an endothermic fuel. A program to develop and demonstrate the endothermic potential of JP-8 for hypersonic scramjet cooling used a high-pressure bench-scale reactor to determine the overall heat sinks (including magnitude of endotherms), endothermic reforming products, and coking rates for this fuel. Endothermic reforming of hydrocarbon fuels is an enabling technology for high-speed flight. The successful implementation of this technology is predicated on the exploitation of existing multi-component fuels and their decomposition with inexpensive, readily available catalysts.

An additive package was developed for JP-8 which offers a  $55\text{ K} = 55\text{ °C}$  ( $100\text{ °F}$ ) increase in the bulk maximum temperature from 436 to 491 K (= from 163 to 218 °C = from 325 to 425 °F) and improves the heat sink capability by 50% [64, 65]. Major advances made during the development of JP-8+100 fuel included the development of several new quantitative fuel analysis tests, a free radical theory of autooxidation, adaptation of new chemistry models to computational fluid dynamics programs, and a non-parametric statistical analysis to evaluate thermal stability. Hundreds of additives were tested for effectiveness, and a package of additives was then formulated for JP-8 fuel. This package has been tested for fuel system materials compatibility and general fuel applicability. The flight testing has shown an improvement in thermal stability of JP-8 fuel. This improvement has resulted in a significant reduction in fuel-related maintenance costs and a threefold increase in mean time between fuel-related failures.

Hydrogen donor compounds and compounds with similar chemical characteristics (decahydroquinoline and cyclodecane) have been used as thermal stabilizers in JP-8+100 fuel. Decalin (a mixture of *cis*- and *trans*-stereoisomers of bicyclo[4.4.0]-

decane) and tetrahydroquinoline (THQ) were evaluated at various concentrations in JP-8+100 fuel and stressed to temperatures up to 873 K (600°C) for 6 h in a flowing reactor system in order to measure thermal oxidative and pyrolytic deposition for all fuel/additives mixtures, the conversion percentages, and composition of the stressed fuel's gaseous and liquid products [66]. *cis*-Decalin and *trans*-decalin were assessed individually to determine whether their thermal stability activities in a static reactor are correlatable to a flowing system and to compare with the performance of the decalin mixture.

The effects of fuel composition changes on jet fuel thermal stability were experimentally investigated [67]. A High Reynolds Number Thermal Stability test device was used to evaluate thermal stability of JP-8 fuels. The experiment consisted of an electrically heated, stainless steel capillary tube with a controlled fuel outlet temperature. An optical pyrometer monitored the increasing external temperature profiles of the capillary tube as deposits build inside during each test. Multiple runs of each fuel composition provided results on measurement repeatability. Testing at two different facilities provided data on measurement reproducibility. The technique was able to distinguish between thermally stable and unstable compositions of JP-8 and intermediate blends made by combining each composition.

### 5.2.6 Oxidation of JP-8

The preignition oxidation reactivity behaviors of five JP-8 samples, three Jet A samples, one JP-7 sample, and four JP-8 surrogate mixtures were studied in a pressurized flow reactor in the low- and intermediate-temperature regime (600–800 K) [68]. No significant differences in the low-temperature oxidation behavior were observed between Jet A and JP-8, suggesting that the two fuels can be used interchangeably for surrogate development.

## 5.3 Toxicity of JP-8

To reduce fuel fouling in US Navy and Air Force aircraft systems and to provide additional heat sink and thermal stability for future systems, the Air Force was developing an improved JP-8 jet fuel called JP-8+100. Two companies developed additive packages that were tested in aircraft systems. To determine whether the additive packages will produce adverse health effects for flightline personnel, acute toxicity testing was performed on JP-8 and two JP-8+100 jet fuels from different suppliers [69]. A single oral dose of 5 mg jet fuel/kg body weight to five male and five female Fischer-344 rats, and a single dermal application of 2 g jet fuel/kg body weight applied to five male and five female New Zealand White rabbits resulted in no deaths. No signs of toxic stress were observed, and all animals gained weight over the 14-day observation periods. Single treatment of 0.5 mL neat jet fuel to rabbit skin produced negative results for skin ir-

ritation. Guinea pigs failed to elicit a sensitization response following repeated skin applications of the jet fuels. Inhalation vapor exposure to JP-8 or JP-8+100 (samples from two different suppliers) resulted in LC50 values of >3.43, >3.52, and >3.57 mg/L, respectively. LC50 values for aerosol exposure to JP-8 and JP-8+100 (samples from two different suppliers) were >4.44, >4.39, and >4.54 mg/L, respectively. Under the conditions of these tests, the additive packages did not potentiate the acute effects normally associated with JP-8 jet fuel exposure.

The relative potency of three jet fuels (JP-4, JP-8, and JP-8+100) to cause respiratory tract sensory irritation was studied by administering vapor only or vapor/aerosol mixtures for 30 min periods by means of a head-only exposure system to groups of four mice [27].

A very detailed summary of toxicity hazards of JP-8 (as well as JP-5 and Jet A) is available from NIOSH Agency for Toxic Substances and Disease Registry, Division of Toxicology and Human Health Sciences [39]. Although JP-8 was identified by the Department of Defense as its single military fuel over 30 years ago, as of 2017 only very little specific data on the toxicity of kerosene-based jet fuels in humans were available. Most of the studies focused on the potential neurotoxicity of JP-8 fuel. Single studies in humans exposed to JP-8 fuel reported increases in white blood cell neutrophil and monocyte levels with no change in lymphocyte subpopulations and an inverse association between aliphatic hydrocarbons in exhaled breath and serum levels of luteinizing hormone. However, exposure to JP-8 was not associated with higher odds of menstrual disorders. Limited information is available on the carcinogenic potential of jet fuels in humans. Studies in laboratory animals have examined the toxicity of JP-8, JP-5, and Jet A fuels following inhalation, oral, or dermal exposure and have reported a number of targets of toxicity, including the lungs, liver, skin, immunological system, nervous system, and developing organism. Although renal effects have also been observed in male rats exposed to JP-8 or JP-5, the lesions are considered to be characteristic of  $\alpha_2\mu$ -globulin nephropathy, which is only observed in male rats and is not considered to be toxicologically relevant to humans. Increases in skin tumors were observed in mice dermally exposed to Jet A for 52–62 weeks; however, tumors were only observed at concentrations resulting in significant skin damage (inflammation and necrosis). Similarly, increased numbers of skin tumors were observed in mice that received applications of undiluted kerosene on the skin for 2 years, but this occurred only in the presence of moderate-to-marked skin damage. No inhalation or oral studies evaluated the carcinogenicity of JP-8, JP-5, or Jet A in laboratory animals; no increases in tumor incidences were observed in rats administered kerosene by gavage for 2 years. No human studies have examined the potential of JP-5, JP-8, or Jet A to induce respiratory effects. Studies in rats, mice, rabbits, and pigs demonstrated the dermal toxicity of topically applied JP-8, JP-5, and Jet A. Similar effects have been observed for all three fuel types.

## 5.4 Safety Properties of JP-8

The US Air Force change from JP-4 to JP-8 was a positive step for aircraft safety but not to the point that fuel fire/explosion safety features such as anti-static additives, fuel tank inerting, explosion suppressant foam, bonding and grounding, and the complete elimination of ignition sources in and around fuel systems can be abandoned.

### 5.4.1 Flash Point of JP-8

An American Society of Testing and Materials (ASTM) test method is used to determine the flash point temperature: The test fuel is placed in a container and slowly and uniformly heated with its temperature monitored. Periodically as the temperature is increased, an ignition source is inserted into the container and this is repeated until the lowest temperature where a flash (light) occurs is identified. This temperature is defined as the flash point temperature. Since this ASTM test is conducted at ambient conditions, the amount of oxygen present is fixed and the ignition source is specified. As the pressure in the fuel tank of aircraft is reduced during aircraft ascent, the effective flash point temperature is lowered. In the case of TWA-800 at 13800 ft, the effective flash point of the fuel was lowered by about 8.3 °C (15 °F). At sea level some fuels may even be non-flammable, but may become flammable at higher altitude.

JP-8 at a specific temperature above its flash point temperature is just as flammable as JP-4 at the same delta temperature above its flash point. The safety advantage of JP-8 over JP-4 is that the ambient temperature and fuel operational temperatures are generally below the flash point of JP-8. The specification MIL-DTL-83133J prescribes a flash point for JP-8 of at least 311 K (38 °C). In the presence of buildup of electrostatic charges, a spark with only 0.20 mJ is sufficient to ignite JP-8 vapors in air.

### 5.4.2 Flammable Range of JP-8 Vapors

The flammable range of JP-8 vapors in air is 0.6–4.7 vol.-%. While it is true that the vapor pressure of JP-8 is less than that of JP-4, it is still possible, given the right conditions, that there are enough explosive vapors in a nearly empty fuel tank with JP-8 fuel to permit ignition that leads to a catastrophic explosion [70, 71].

By the mid 1990s most Air Force bases changed to JP-8, which resulted in a reduction of aircraft mishaps and damage caused by fuel combustion as the initial cause or as a secondary effect. Obviously under the right circumstances all fuels burn. A perfect example is the TWA-800 accident (17 July 1996) in which 230 people perished as a result of an in-flight explosion of the aircraft's center wing tank. While the tank contained only unusable fuel, it was in fact the vapors from Jet A (a fuel which exhibits very similar physical properties and combustion characteristics as JP-8) which exploded in the empty portion of the tank known as the "ullage."

Whatever ignited the fuel vapor/air mixture may never be determined; however, the fact that a catastrophic explosion occurred with Jet A fuel is significant in that a similar set of circumstances can potentially also occur with JP-8 and cause the same tragic results. The safety advantage of JP-8 over JP-4 is that the ambient temperature and fuel operational temperatures are generally below the flash point of JP-8.

Both the Air Force and commercial aircraft operators would prefer a fuel like JP-5 with a flash point above 333 K (140 °F), but JP-5 fuel availability is scarce and cost is prohibitive. Although Navy aircraft currently operate on JP-5 fuel, the Navy still expends significant effort addressing aircraft fire issues.

## 5.5 Fuel Mixtures with JP-8

Fuel mixtures with JP-8 were often evaluated as a means of increasing the heat of combustion of JP-8 or lowering the freezing points of other fuels. Fuel mixtures of JP-8 with other fuels include those with high-density terpene dimer fuels [72].

### 5.5.1 Gelled Kerosene JP-8

Fumed silica, also known under the trade name Cab-O-Sil<sup>®</sup>, is a useful gelling agent for fuels as well as oxidizers. The rheological behavior of gelled JP-8 turbine fuel with fumed silica as a gelling agent was measured and the optimal gel mixing process, gel stability, and rheological parameters showed a significant influence of the added silica amount [73, 74].

The rheological behavior of gelled rocket propellant RP-1 and JP-8 with fumed silica as a gelling agent has been measured and an optimal mixing process has been selected. The rheological parameters of the gelled kerosene showed a significant influence of the added amount of silica in comparison to the ungelled pure liquids [75] (Figure 12).

The rheology and droplet burning behaviors of JP-8 gelled with fumed silica were compared to those of methylhydrazine (MMH) gelled with hydroxypropyl cellulose [76]. Droplets of gelled MMH burning in air swelled and had a flexible droplet surface, whereas burning kerosene droplets gelled with fumed silica had a rigid silica structure which remained unburned.

The droplet burning of gelled JP-8 in air was studied at ambient pressure [77]. Based on a rheological characterization of gelled JP-8 turbine fuel using fumed silica as a gelling agent, single droplet combustion experiments have been conducted. Combustion experiments have shown a typical  $d^2$ -law behavior with considerable influence of the gelling agent. A higher amount of gellant agent resulted in a reduced burning rate. Droplet size as well as droplet temperature during combustion depended strongly on the consistency of the gel.

**Figure 12:** Viscosity of gelled JP-8 as a function of shear rate and silica amount. (Reproduced and modified from [75] with permission from W. E. Anderson.)

Gelled JP-8 has been used to study the rheological behavior of gelled hydrocarbons using 4 to 7 mass-% of fumed silica as the gelling agent [78]. Viscosity, stability, thixotropic behavior, and the viscoelastic properties of the gel through their storage and loss moduli were measured as a function of the amount of gelling agent added. Differential scanning calorimetry measurements showed only a slight influence of the amount of gelling agent on the enthalpy of vaporization of the gels. The ungelled hydrocarbons had a higher enthalpy of vaporization than the gels.

### 5.5.2 Injectors for Gelled Kerosene JP-8

Gelled fuels may be safer to handle, but they are more difficult to burn and to atomize into small droplets. One type of injector that has been tested for gelled propellants is the like-on-like impinging jet injector [79]. Disintegration of individual water jets and liquid sheets formed by jet-on-jet impingement was studied with jet velocities in the range of 0.9–37 m/s (3–122 feet/s) and compared to known water correlations for selected velocities. The laminar sheet shape is predicted and compared to high speed images of the experimental sheet to help ensure proper alignment and operation of the impinging jet system. A JP-8 and 5% fumed silica gelled mixture impingement study was conducted as a first step toward producing and injecting gelled hypergolic bipropellant reactants through this injector. The gelled-impingement sheet disintegration was observed and compared to water data collected in the same apparatus.

## 6 Jet Fuel JP-9

JP-9 is a blend of the three components and was developed to meet the requirements for an air-launched cruise missile. JP-9, a three-component blend consisting of 65–70% JP-10, 10–12% methylcyclohexane to increase volatility, and 20–25% RJ-5 (to be described in *Encyclopedia of Liquid Fuels*, chapter “Ramjet Fuels”) to boost energy content, was developed to meet the fuel specifications; its properties are described in Table 9. This fuel is not practical because of the high cost and abandonment of RJ-5 supply route.

**Table 9:** Physical properties of JP-9.

| Property                                 | SI units                                          | Other units                                                 | References |

### 6.1 Preparation of JP-9

JP-9 can be prepared by mixing 65–70 mass-% JP-10, 20–25 mass-% RJ-5, and 10–12 mass-% methylcyclohexane. In an effort to measure physical properties of JP-9 within the range of MIL-SPEC tolerances as a function of composition, 12 JP-9 mixtures were made starting with four different batches of RJ-5 [80]. Blends of the

fuel components were prepared which covered but did not exceed the specified composition range for JP-9 fuel.

## 6.2 Physical Properties of JP-9

Physical properties of JP-9 are summarized in Table 9 and reference [81].

### 6.2.1 Thermodynamic Properties of JP-9

#### 6.2.1.1 Heat Capacity of JP-9

The heat capacity of JP-9 as a function of temperature between 260 and 360 K can be calculated from the following equation [83]:

$$c_p = 0.09299 + 0.001006 T$$

where  $c_p$  is the heat capacity in  $\text{cal g}^{-1} \text{ } ^\circ\text{C}^{-1}$  and  $T$  is the temperature in kelvin.

#### 6.2.1.2 Heat of Combustion of JP-9

The gross heat of combustion of JP-9 is  $44.711 \pm 0.003 \text{ kJ/kg}$  ( $10686.16 \pm 0.78 \text{ cal/g}$ ), and the net heat of combustion of JP-9 is  $42.21 \pm 0.01 \text{ kJ/kg}$  ( $10089.5 \pm 2.4 \text{ cal/g}$ ) [83]. An earlier report from the same source gave the heat of combustion of JP-9 as  $10089.3 \pm 2.4 \text{ cal/g}$  [84].

## 6.3 Chemical Properties of JP-9

The empirical formula of JP-9 is  $\text{C}_{10.2}\text{H}_{16}$ . The chemical composition of JP-9 is 65–70 mass-% JP-10, 20–25 mass-% RJ-5, and 10–12 mass-% methylcyclohexane. An out-of-date specification MIL-P-87107B (USAF) (March 1979) once covered both JP-9 and JP-10 but it has been superseded by MIL-DTL-87107E [82] which covers JP-10 only.

## 6.4 Safety Properties of JP-9

### 6.4.1 Fire Hazard Properties of JP-9

The flash point of JP-9 per MIL-P-87107B was supposed to be between 16 and 27°C (60 and 80 °F).

### 6.4.2 Environmental Impact of JP-9 Spills

JP-9 and several other kerosenes were examined to measure the effects of potential environmental contamination resulting from these fuels on fresh water fish and aufwuchs [28]. Besides JP-4, the materials evaluated included RJ-4, RJ-5, methylcyclohexane, and JP-4.

## 7 Jet Fuel JP-10

JP-10 is a military missile fuel, used in many cruise missiles (e.g., Tomahawk, ALCM, ACM). JP-10 is a single component fuel, *exo*-tetrahydro-di(cyclopentadiene), *exo*-tricyclo[5.2.1.0<sup>2,6</sup>]decane, in contrast to the other, JP-type jet fuels (e.g., JP-8 or JP-7) which are multi-component petroleum distillates. JP-10 is a single component (*exo*-)isomer. The *endo*-isomer is a solid at room temperature and is not used for JP-10. JP-10 has a very low freezing point (194 K = -79 °C) and a density almost 20% higher than JP-8. The main ingredient of JP-10 consists mostly of *exo*-tetrahydro-dicyclopentadiene, C<sub>10</sub>H<sub>16</sub>, CAS RN [2825-82-3], which is a synthetic isocyclic (alicyclic) hydrocarbon (see chapter “Cycloaliphatic Hydrocarbons”). JP-10 per MIL-DTL-87107E may contain antioxidant and fuel system icing inhibitors, which may slightly change its physical and chemical properties.

### 7.1 Production of JP-10

JP-10 is made by adding 90–110 ppm (by mass) antioxidant and 0.10–0.15 vol.-% fuel system icing inhibitors to *exo*-tetrahydrodicyclopentadiene.

### 7.2 Physical Properties of JP-10

Physical properties of JP-10 are summarized in Table 10 and would be mostly identical with the properties of *exo*-tetrahydrodicyclopentadiene (chapter “Cycloaliphatic Hydrocarbons”). Based on their titles, many publications describe the chemical studied as JP-10, but it is doubtful that they actually had military grade JP-10 with antioxidant and icing inhibitor in their laboratory. Most of those experiments were probably made with more or less pure *exo*-tetrahydrodicyclopentadiene without any additives. Not knowing the actual composition of the samples tested (additives or no additives), we have entered references to the publications into those sections where the title of the publication directed us to. This may result in publications with properties of otherwise identical chemicals to be found in different sections of this book. Thus, one will want

**Table 10:** Physical properties of JP-10.

to examine both sections, this one under JP-10 here and the other in the section on *exo*-tetrahydrodicyclopentadiene. The two sections will complement each other and there may be some duplication of information.

The physical properties of *exo*-tetrahydrodicyclopentadiene (THDCPD) as a pure compound (without any additives) are described in chapter “Cycloaliphatic Hydrocarbons.” A very detailed characterization of thermochemical and thermophysical properties of JP-10 performed in 2006 was done on JP-10 samples taken from the flight line, but it was not known whether this particular sample contained any additives or not [85]. Most likely they did contain additives and the investigator should have identified them.

### 7.2.1 Freezing Point of JP-10

The freezing point of JP-10 is not specified by MIL-DTL-87107E but must not be higher than 183.2 K ( $-89.9^{\circ}\text{C}$ ). However, one source [89] gave the freezing point of JP-10 as

194 K (−79 °C), which is higher than the temperature found in other sources. One source measured the freezing point of JP-10 at 200 K (−73 °C). JP-10 was added to RJ-5 in an effort to lower the freezing point of RJ-5. The freezing points of XTHDCPD/PHDNBD (JP-10/RJ-5) mixtures were measured over a wide range of compositions [90]. There was very little difference among the viscosity-composition isotherms for the three PHDNBD isomers.

### 7.2.2 Density of JP-10

The density of JP-10 specified per MIL-DTL-87107E is 0.934–0.943 g/cm<sup>3</sup> at 288 K (15 °C). Dicyclopentadiene and dimethylcyclopentadiene, for example, have comparable high densities of 0.974 and 0.940 g/cm<sup>3</sup>, respectively, at 293 K (20 °C), while the densities of gasoline and aviation fuel kerosene are substantially lower. The density of JP-10 as a function of temperature is listed in Table 11.

**Table 11:** Density of JP-10 as a function of temperature.

| Temperature |    | Density           |
|-------------|----|-------------------|
| K           | °C | g/cm <sup>3</sup> |
| 278         | 5  | 0.9462            |
| 288         | 15 | 0.9377            |
| 298         | 25 | 0.9314            |
| 318         | 45 | 0.9166            |
| 338         | 65 | 0.9017            |

Data source: [87]

The density and the absolute and kinematic viscosity of JP-10 in the temperature range from 233–373 K (−40 to +100 °C) at atmospheric pressure was measured in a Stabinger viscodensimeter (Anton Paar SVM 3000) as well as a Sound Speed Analyzer DSA 5000 [85]. The density decreased almost linearly with temperature, as shown in Figure 13.

The density of JP-10 was expressed by the polynomial equation

$$\rho = a_0 + a_1\tau + a_2\tau^2$$

where  $\rho$  is the density in g/cm<sup>3</sup> and  $\tau = T/T_c$  is the reduced temperature (temperature divided by the critical temperature) and  $a_0$ ,  $a_1$ , and  $a_2$  are constants:  $a_0 = 1153.0412$ ;  $a_1 = -192.47447$ ;  $a_2 = -9.3825928$ .

Densities of JP-10 at temperatures from 270 to 470 K and at pressures up to 30 MPa were measured with two vibrating-tube densimeters [89]. Correlations were reported that represented the temperature and pressure dependence of the experimental density data within their estimated uncertainty. The properties of JP-10 were compared to

**Figure 13:** Density of JP-10 as a function of temperature. (Reproduced and modified from [85].)

those of other previously measured jet and rocket fuels, such as RP-1 and Jet A. The density of JP-10 is much higher than the density of RP-1 (Figure 14).

Density data for compressed JP-10 were correlated with a Tait equation

$$\rho = \frac{\rho_{\text{ref}}}{1 - C \ln\left(\frac{P + D}{P_{\text{ref}} + D}\right)}$$

where  $\rho$  is the density in  $\text{g/cm}^3$ ,  $\rho_{\text{ref}}$  is the density at the reference state,  $P$  is the pressure in MPa,  $P_{\text{ref}}$  is the reference pressure = 0.083 MPa, and  $C$  is a constant  $C = 79.18232 \times 10^{-3}$ .  $D$  is the Tait parameter to be calculated from a quadratic polynomial

$$D = 417.1 - 370.4 \times T_r + 86.24 \times T_r^2$$

where  $T_r$  is the reduced absolute temperature  $T$  divided by 273.15 K.

The density of JP-10 at 267 to 873 K under pressures of 0.70 to 6.00 MPa was measured using a gamma-ray radial method calibrated with water, cyclohexane, and a mixture of *n*-heptane and *n*-octane [91]. This method was based on the attenuation theory of gamma rays. Two empirical correlations were used to fit the liquid and gas density data separately. The isobaric thermal expansion of the liquid was calculated. The densities of liquid JP-10, ranging from 267.9 to 562.1 K under 0.70 MPa, 267.3 to

**Figure 14:** Measured and extrapolated density data of JP-10 compared to those of other fuels as a function of temperature at ambient pressure. (Reprinted and adapted from [89], with permission from ©2011 American Chemical Society; permission conveyed through RightsLink.)

563.8 K under 1.48 MPa, 267.9 to 651.9 K under 3.06 MPa, and 267.3 to 681.8 K under 6.00 MPa, were fitted by third-order polynomials as

$$\rho = 1853.6 - 6.4515T + 0.0153T^2 - 1.3517 \times 10^{-5}T^3$$

where  $\rho$  represents density of liquid JP-10 in  $\text{kg/m}^3$ , and  $T$  represents temperature in kelvin. The predicted density curves in different colors versus temperature under different pressures and measured density points under experimental pressures are shown in Figure 15.

The density of subcritical JP-10 under saturated vapor pressure conditions was calculated and is illustrated in Figure 16. For comparison, the vapor–liquid coexistence plot given in Figure 16 shows a critical temperature,  $T_c = 698 \text{ K}$ , with a corresponding critical density  $\rho_c = 285 \text{ kg/m}^3$ . Similar charts are available for tetralin and toluene.

**Figure 15:** Predicted density curves of JP-10 versus temperature under different pressures and measured density points under experimental pressures. (Reprinted and adapted from [91] with permission from ©2019 American Chemical Society; permission conveyed through RightsLink.)

**Figure 16:** Vapor–liquid coexistence region of JP-10. (Reproduced and modified from [92].)

### 7.2.3 Vapor Pressure of JP-10

The vapor pressure of JP-10 is governed by its main ingredient, *exo*-tetrahydrodicyclopentadiene (see chapter “Cycloaliphatic Hydrocarbons”). The vapor pressure of JP-10 determined in an apparatus with a vapor : liquid volume ratio of 0.28 is listed in Table 12.

**Table 12:** Vapor pressure of JP-10 as a function of temperature.

| Temperature |    | Vapor pressure |       |
|-------------|----|----------------|-------|
| K           | °C | kPa            | mm Hg |
| 273         | 0  | 4.26           | 32    |
| 298         | 25 | 5.73           | 43    |
| 323         | 50 | 8.26           | 62    |
| 348         | 75 | 13.3           | 100   |

Data source: [87]

The dependence of the vapor pressure of JP-10 on temperature can be expressed by a Cox equation

$$\ln(P/P_c) = (1 - 1/T_r) \exp(2.39742 - 1.28961T_r + 0.90779T_r^2)$$

where the reduced temperature is  $T_r = T/T_c$ ,  $T$  is the temperature in kelvin,  $T_c$  is the critical temperature = 698 K and  $P_c$  is the critical pressure = 3733 kPa [92]. Figure 17 shows experimental data for measured vapor pressure of JP-10.

**Figure 17:** Vapor pressure of JP-10 as a function of temperature. (Reproduced and modified from [93].)

#### 7.2.4 Velocity of Sound and Compressibility of JP-10

A sound speed analyzer (Anton Paar DSA 5000) was used to measure the velocity of sound and the density of several JP-10 samples at atmospheric pressure in the temperature range 278–343 K (5–70 °C) [85]. The velocity of sound decreased almost linearly with temperature (Figure 18).

**Figure 18:** Velocity of sound in JP-10 as a function of temperature. (Reproduced and modified from [85].)

The adiabatic compressibility of JP-10 was derived from velocity of sound data using the known correlation between the two properties (Figure 19). Adiabatic compressibilities were calculated from the measured densities and velocity of sound according to the thermodynamic relation

$$k_s = -\frac{\left(\frac{\partial V}{\partial P}\right)_s}{V} = \frac{1}{\rho w^2}$$

where  $V$  denotes volume,  $P$  is the pressure,  $\rho$  is the density, and  $w$  is the velocity of sound. The subscript  $s$  indicates “at constant entropy.”

**Figure 19:** Adiabatic compressibility of JP-10 as a function of temperature. (Reproduced and modified from [85].)

The velocity of sound in JP-10 was measured with a propagation time method at ambient pressure from 278 to 343 K [89]. The results for density and velocity of sound at ambient pressure were combined to obtain the adiabatic compressibility. The velocity of sound properties of JP-10 were compared to those of other previously measured jet and rocket fuels such as RP-1 and Jet A (Figure 20). The velocity of sound in JP-10 is higher than the velocity of sound in other fuels.

### 7.2.5 Viscosity of JP-10

The viscosity of *exo*-THDCPD and its mixtures with PHDNBD was measured over a wide range of temperatures. The kinematic viscosity of JP-10 as a function of temperature is listed in Table 13.

**Figure 20:** Measured velocity of sound data of JP-10 as a function of temperature at ambient pressure compared to those of other jet fuels. (Reprinted and adapted from [89], with permission from ©2011 American Chemical Society; permission conveyed through RightsLink.)

**Table 13:** Viscosity of JP-10 as a function of temperature.

| Temperature |      | Kinematic viscosity |      |
|-------------|------|---------------------|------|
| K           | °C   | mm <sup>2</sup> /s  | cSt  |
| 253         | −20  | 8.84                | 8.84 |
| 273         | 0    | 5.08                | 5.08 |
| 294.2       | 21.1 | 3.26                | 3.26 |
| 310.9       | 37.8 | 2.37                | 2.37 |

Data source: [87]

The viscosity of JP-10 was measured with a Stabinger viscodensimeter SVM 3000 on three samples from the same stock to assess the repeatability of the instrument [85]. Four runs were carried out in the combined temperature range from 233 to 373 K. The dynamic viscosity curve as a function of temperature measured in the Stabinger viscodensimeter SVM 3000 is shown in Figure 21. The measurement data points fall on top of each other, showing good reproducibility. Two standard fluids, one more viscous and one less viscous, were tested to calibrate and verify proper operation of the instrument.

**Figure 21:** Dynamic viscosity of JP-10 as a function of temperature. (Reproduced and modified from [85].)

The viscosities of JP-10 were measured using a two-capillary method at 242.7–753.3 K under pressures of 0.69–6 MPa [94]. After the viscosity of pure *n*-octane was measured and compared with literature data, the measurement system was calibrated, and the average absolute deviation and the maximum absolute deviation were found to be 0.71 and 1.35%, respectively. Yaws' equation and Bruno's equation were used to cor-

**Figure 22:** Viscosity of JP-10 at 3 MPa as a function of temperature. (Reprinted and adapted from [94], with permission from ©2017 American Chemical Society; permission conveyed through RightsLink.)

relate the experimental data. The data measured at a pressure of 3 MPa are shown in Figure 22. The data extend into the critical region.

### 7.2.6 Surface Tension of JP-10

The surface tension of JP-10 is listed in Table 14.

**Table 14:** Surface tension of JP-10 as a function of temperature.

| Temperature |    | Surface tension |        |
|-------------|----|-----------------|--------|
| K           | °C | N/m             | dyn/cm |
| 298         | 25 | 0.0321          | 32.1   |
| 323         | 50 | 0.0298          | 29.8   |
| 348         | 75 | 0.0274          | 27.4   |

Data source: [87]

### 7.2.7 Pressurant Gas Solubility in JP-10

The solubility of nitrogen, oxygen, and carbon dioxide in JP-10 (*exo*-tetrahydrodicyclopentadiene) in the temperature range from 293 to 343 K was measured in intervals of

10 K and in the pressure range from 0.5 to 7.5 MPa [95]. The solubility of the three gases in JP-10 in the studied temperature and pressure range decreased in the order carbon dioxide > oxygen > nitrogen. Henry's constants and the thermodynamic properties of solvation were calculated from the solubility data.

### 7.2.8 Thermal Conductivity of JP-10

Transient hot-wire measurements of the thermal conductivity of the JP-10 liquid sample were made along 11 isotherms at temperatures from 300 to 500 K with pressures up to 30 MPa [85]. The thermal conductivity was illustrated in Figure 23 as a function of density, not temperature. This is not a very convenient format if the user needs thermal conductivity as a function of temperature at constant pressure (sea level atmospheric pressure).

**Figure 23:** Thermal conductivity of JP-10 as a function of density. (Reproduced and modified from [85].)

### 7.2.9 Thermodynamic Properties of JP-10

Thermodynamic properties of pure *exo*-tetrahydrodicyclopentadiene, the main constituent of JP-10, are discussed in chapter “Cycloaliphatic Hydrocarbons.” Since JP-10 is 99+% *exo*-tetrahydrodicyclopentadiene, its thermodynamic properties will be the same as those of *exo*-tetrahydrodicyclopentadiene. A very detailed characterization

of thermodynamic properties of JP-10 was done on a sample of JP-10 taken from the flight line, but it was not known whether this particular sample contained any additives or not [85].

### 7.2.9.1 Heat Capacity of JP-10

A high-temperature/high-pressure sample cell developed for use with a DSC has been used to determine the liquid-phase heat capacities and critical properties for toluene, tetralin, and JP-10 [92]. The results for toluene and tetralin compared very favorably with available literature values, while no reliable literature data for JP-10 to compare to were available.

The results of heat capacity measurements of subcritical JP-10 at saturation pressure between 300 and 690 K were only given in table format (Table 15) [92]. It would have been more practical to give the parameters for a curve-fitted polynomial equation.

The heat capacity of JP-10 as a function of temperature in the range 260–465 K can be expressed by the following equation [88]:

$$c_p = 0.10423 + 0.76872 \times 10^{-3}T + 0.46992 \times 10^{-6}T^2$$

**Table 15:** Heat capacity of JP-10 at constant volume and under saturation pressure conditions.

| Temp., K | $C_V/R$ | $C_\sigma/R$ | Temp., K | $C_V/R$ | $C_\sigma/R$ |
|----------|---------|--------------|----------|---------|--------------|
| 300      | 27.37   | 27.37        | 500      | 40.60   | 40.67        |
| 310      | 28.11   | 28.11        | 510      | 41.21   | 41.30        |
| 320      | 28.83   | 28.83        | 520      | 41.82   | 41.93        |
| 330      | 29.55   | 29.55        | 530      | 42.43   | 42.56        |
| 340      | 30.25   | 30.25        | 540      | 43.04   | 43.20        |
| 350      | 30.95   | 30.95        | 550      | 43.66   | 43.85        |
| 360      | 31.64   | 31.64        | 560      | 44.28   | 44.52        |
| 370      | 32.32   | 32.32        | 570      | 44.91   | 45.20        |
| 380      | 32.99   | 32.99        | 580      | 45.55   | 45.91        |
| 390      | 33.65   | 33.66        | 590      | 46.22   | 46.66        |
| 400      | 34.31   | 34.32        | 600      | 46.90   | 47.45        |
| 410      | 34.96   | 34.97        | 610      | 47.61   | 48.30        |
| 420      | 35.61   | 35.62        | 620      | 48.37   | 49.22        |
| 430      | 36.25   | 36.26        | 630      | 49.17   | 50.25        |
| 440      | 36.88   | 36.90        | 640      | 50.03   | 51.44        |
| 450      | 37.51   | 37.53        | 650      | 50.99   | 52.85        |
| 460      | 38.14   | 38.17        | 660      | 52.06   | 54.62        |
| 470      | 38.76   | 38.79        | 670      | 53.29   | 57.05        |
| 480      | 39.38   | 39.42        | 680      | 54.80   | 60.96        |
| 490      | 39.99   | 40.05        | 690      | 56.86   | 70.62        |

$R = 8.31441 \text{ J K}^{-1} \text{ mol}^{-1}$ ; Subscript  $\sigma$  = saturation pressure conditions

Data source: [92]

where  $c_p$  is the heat capacity in  $\text{cal g}^{-1} \text{ } ^\circ\text{C}^{-1}$  and  $T$  is the temperature in kelvin. For a temperature of 298 K, this equation gives a heat capacity of  $1.569 \text{ J g}^{-1} \text{ K}^{-1} = 0.375 \text{ cal g}^{-1} \text{ } ^\circ\text{C}^{-1}$

#### 7.2.9.2 Enthalpy of Formation of JP-10

Literature data for the enthalpy of formation of JP-10 differ substantially:  $-902 \text{ J/g} = -388 \text{ BTU/lb}$  [6] and  $-774 \text{ J/g} = -185 \text{ cal/g}$  for a fuel with a density of  $0.0336 \text{ lb}_m/\text{in.}^3$  given in [14]. The enthalpy of formation of JP-10 would essentially be identical with that of *exo*-tetrahydrodicyclopentadiene for which a heat of combustion of  $10682.01 \pm 0.90 \text{ cal/g} = 1457.68 \pm 0.33 \text{ kcal/mol}$  was reported which leads to an enthalpy of formation of  $-122.8 \pm 1.5 \text{ kJ/mol} = -29.35 \pm 0.35 \text{ kcal/mol} = -901 \text{ J/g} = -215 \text{ cal/g}$  [84].

#### 7.2.9.3 Enthalpy of Fusion of JP-10

The heat of fusion of JP-10 would essentially be the same as that of *exo*-tetrahydrodicyclopentadiene which is  $1.2 \text{ kJ/mol}$  at  $183.2 \text{ K}$ .

#### 7.2.9.4 Enthalpy of Evaporation of JP-10

The enthalpy of evaporation of JP-10 would essentially be the same as that of *exo*-tetrahydrodicyclopentadiene which is  $53.4 \pm 0.8 \text{ kJ/mol}$  ( $10.40 \pm 0.2 \text{ kcal/mol}$ ) at  $443 \text{ K}$  [96].

#### 7.2.9.5 Heat of Combustion of JP-10

The upper heat of combustion of JP-10 was measured at  $42.81 \text{ MJ/kg}$  [87].

#### 7.2.10 Index of Refraction of JP-10

The index of refraction of JP-10 was reported as  $n_D^{20} = 1.4872$  [97].

#### 7.2.11 Critical Point Properties of JP-10

The following values of the critical parameters should be used for all property calculations from the equation of state:

- $T_c = 698 \text{ K}$
- $P_c = 3.733 \text{ MPa}$
- $\rho_c = 2.16 \text{ mol/dm}^3$

while other sources [92] gave the critical point properties of JP-10 as

- $T_c = 698 \text{ K}$
- $P_c = 3.733 \text{ MPa}$
- $\rho_c = 285 \text{ kg/m}^3$

### 7.2.12 Molecular Structure of JP-10

Some publications deal with the molecular structure of what the authors called “JP-10.” There is no molecular structure of JP-10 because in the exact sense of the definition JP-10 is a mixture and not a pure compound. The molecular structure of *exo*-tetrahydrodicyclopentadiene (tricyclo[5.2.2.1.0<sup>2,6</sup>]decane) is discussed in chapter “Cycloaliphatic Hydrocarbons.”

## 7.3 Physical Properties of JP-10 Mixtures

Numerous mixtures of JP-10 with other hydrocarbons have been characterized in an effort to develop improved or more economical fuels for cruise missiles and other air-breathing propulsion applications. The densities and viscosities of the binary mixtures of JP-10 with *n*-octane and JP-10 with *n*-decane were determined from 293.15 to 313.15 K at atmospheric pressure, over the entire composition range [98]. Excess volumes  $V_m^E$  of the binary mixtures were calculated. The experimental data indicated that the addition of *n*-alkanes has a distinct effect on the density and viscosity of JP-10, and  $V_m^E$  values of the binary systems were negative. Experimental data were fitted to the Redlich–Kister equation, and the adjustable parameters and the standard deviations between experimental and calculated values were estimated. Viscosity data have been correlated with several semi-empirical equations, and the Grunberg–Nissan equation gave satisfactory results.

Densities and viscosities of *exo*-tetrahydrodicyclopentadiene plus *n*-undecane and *exo*-tetrahydrodicyclopentadiene plus *n*-tetradecane mixtures were measured at different temperatures (293, 298, 303, and 313 K) and atmospheric pressure over the entire composition range [99]. The excess molar volumes ( $V_m^E$ ) and deviations in viscosity  $\delta\eta$  for the mixtures were calculated from the experimental data and fitted to the Redlich–Kister equation, and the regression coefficients and the standard deviations of the fits were given. The viscosity data were correlated with several semi-empirical equations, and the double-parameter McAllister equation gave satisfactory results. Similar experiments were conducted with mixtures of *exo*-tetrahydrodicyclopentadiene with *n*-butanol and *exo*-tetrahydrodicyclopentadiene with *n*-pentanol [100]. Similar experiments were conducted with mixtures of *exo*-tetrahydrodicyclopentadiene with methyl *tert*-butyl ether or ethyl *tert*-butyl ether [101]. The excess molar volumes were negative over the entire range of composition.

Bubble-point vapor pressures and densities for the binary mixtures of propylene glycol monomethyl ether (PGME) and *exo*-tricyclo[5.2.1.0<sup>2,6</sup>]decane (JP-10) were measured over the whole composition range [102]. The Antoine equation was fitted to the experimental vapor pressure data and the parameters were calculated. The excess molar volumes for the mixtures were calculated from the density data and were negative. The flash points of the binary mixtures of PGME and JP-10 were measured by a closed-

cup flash point analyzer and predicted from vapor pressures using Wilson and the regular solution models. It was found that PGME can effectively adjust the volatility and flash point of hydrocarbon fuels.

The thermal decomposition of JP-10, *iso*-octane and their mixtures was examined in a stainless steel tubular reactor at temperatures from 883 to 963 K [103]. The conversions of components, and the yields of gas and liquid products for each sample were determined in detail. The addition of *iso*-octane can promote the decomposition of JP-10. One possible mechanism has been proposed to demonstrate the initiation effect of *iso*-octane on the decomposition of JP-10. For the possible pathways, the rate constants of the H-abstraction reactions between the alkyl radicals obtained from C—C bond fission of *iso*-octane and the H atoms of JP-10 were calculated using density functional theory (DFT). Combining the quantum calculations and experimental observations, the formation of some decomposition products in the JP-10/*iso*-octane mixtures can be predicted.

## 7.4 Chemical Properties of JP-10

The chemical gross formula for THDCPD, the main ingredient of JP-10, is  $C_{10}H_{16}$  with 11.84 mass-% hydrogen and a molecular mass of 136.24 g/mol. THDCPD is an isomer of adamantane, limonene, pinene, and camphene.

### 7.4.1 Composition of JP-10

The main ingredient of JP-10 is *exo*-tetrahydrodicyclopentadiene (*exo*-THDCPD), also described as tricyclo[5.2.1.0<sup>2,6</sup>]decane. The properties of THDCPD as a pure compounds are described in chapter “Cycloaliphatic Hydrocarbons.” JP-10 may contain 90–110 ppm (by mass) of an antioxidant. JP-10 may contain a 0.10–0.15 vol.-% of a fuel system icing inhibitor (FSII). JP-10 is not a complex mixture but rather a simple fluid where the major “impurity” is typically the *endo* isomer.

A sample of JP-10 analyzed at NIST by GC-MS contained 1% adamantane and 2.5% of the *endo* isomer of tetrahydrodicyclopentadiene which eluted after the main peak of *exo*-tetrahydrodicyclopentadiene [85]. In addition, there were several peaks of trace contaminants eluting ahead of *exo*-tetrahydrodicyclopentadiene, the main peak in this category was decahydronaphthalene (decalin). Other trace contaminants included 2-methyl-bicyclo[3.2.1]octane, 2-ethyl-bicyclo[2.2.1]heptane, *endo*-2,2,3-trimethyl-bicyclo[2.2.1]heptane, *cis*-1methyl-4-(1-methylethenyl)cyclohexane and 2,6-dimethyl-bicyclo[3.2.1]octane.

### 7.4.2 Specification Requirements for JP-10

Specification requirements for JP-10 are listed in MIL-DTL-87107E [82].

#### 7.4.2.1 Antioxidants

The following active inhibitors shall be blended separately or in combination into the fuel in total concentration of 90 parts per million (minimum) to 110 parts per million (maximum), by weight, not including weight of solvent, in order to prevent the formation of polymeric oxidation products:

- a. 2,6-*tert*-butyl-4-methylphenol
- b. 6-*tert*-butyl-2,4-dimethylphenol
- c. 2,6-di-*tert*-butylphenol

#### 7.4.2.2 Fuel System Icing Inhibitor

Fuel system icing inhibitor (FSII) shall only be used at the request of the user. When requested by the user, the FSII shall conform to MIL-DTL-85470. The requirement for adding fuel system icing inhibitor to JP-10 was eliminated during revision D of MIL-DTL-87107D.

#### 7.4.3 Thermal Decomposition of JP-10

This section overlaps significantly with chapter “Cycloaliphatic Hydrocarbons” about the thermal decomposition of *exo*-tetrahydrodicyclopentadiene (THDCPD). Most investigators made no distinction between JP-10 and pure THDCPD when actually JP-10 may contain additives that influence its thermal decomposition and autoxidation behavior.

The thermal decomposition of JP-10 has been thoroughly investigated. The literature references to numerous publications on experimental studies of JP-10 decomposition are discussed here in chronological order. There is also a section on theoretical studies on JP-10 decomposition (Section 7.4.3.3).

Establishment of an accurate kinetic mechanism for JP-10 pyrolysis and oxidation would require identification of the initial products of JP-10 thermal decomposition. A high-speed UV absorption kinetic spectrograph can be used with a tube to rapidly acquire spectra to measure and identify these initial products at combustion temperatures [104]. Using this kinetic spectrograph, the high-temperature UV absorption spectra for a variety of hydrocarbon species related to the decomposition of JP-10 have been measured. These species included benzene, cyclopentene, propene, ethylene, 1,3-butadiene, cyclopentadiene, and undecomposed JP-10. Few of these spectra had been previously measured at high temperature. By comparison of these spectra to the absorption spectrum of JP-10 decomposition products, evidence of cyclopentene as an initial decomposition product with near unity yield was found.

The thermal decomposition of JP-10 at 623–698 K (350–425 °C) was studied by enclosing samples in CRES-316L stainless steel bomblets (“cells”) consisting of 6.4 cm lengths of high pressure tubing (0.64 cm external diameter, 0.18 cm internal

diameter) that were sealed on one end with a stainless steel plug welded by a clean tungsten-inert-gas (TIG) process [85]. Each cell was connected to a high-pressure valve at the other end. Each cell and valve was capable of withstanding a pressure in excess of 105 MPa at the desired temperature. The cells were maintained at the reaction temperature for a specified period of time ranging from 4 min to 20 h. After the desired time period, the cells were removed from the thermal block and quenched in water at room temperature. The thermally stressed JP-10 was then recovered from the cells and analyzed by GC-MS. The early eluting pyrolysis products were *n*-propane, *n*-butane, cyclopentane, methyl cyclopentane, 1-methyl cyclopentene, benzene, ethyl cyclopentane, ethylidene cyclopentane, toluene, *n*-propyl cyclopentane, *cis*-bicyclo[3.3.0]oct-2-ene, ethyl benzene, *o*-xylene, octahydropentylene, and 3-methyl cyclooctane. The thermal decomposition reaction rate constants were 648 K (375 °C)  $0.00111 \text{ min}^{-1}$ , 673 K (400 °C)  $0.00437 \text{ min}^{-1}$ , 698 K (425 °C)  $0.01518 \text{ min}^{-1}$ .

The product distribution and kinetics of thermal cracking of JP-10 were investigated in an annular tubular reactor at atmospheric pressure in the temperature range of 903–968 K [105]. No inerts were added as diluents to the feed stream entering the reactor. The major decomposition products were methane, ethylene, propylene, cyclopentene, cyclopentadiene, benzene, and toluene. The pre-exponential factor, activation energy, and overall reaction order for thermal cracking of JP-10 were determined by non-linear regression analysis to be  $2.4 \times 10^{13} (\text{m}^3/\text{mol})^{0.1} \text{ s}^{-1}$ , 256.2 kJ/mol, and 1.1, respectively.

The decomposition of JP-10 was studied in a small flow tube pyrolysis reactor over the temperature range up to 1700 K with reactor dwell times on the millisecond time scale [106]. For comparison, the decomposition behavior of cyclopentadiene, dicyclopentadiene, and benzene was studied under identical conditions. Products of pyrolysis were identified by chemical ionization and electron impact ionization mass spectrometry. On the experimental time scale, JP-10 began to decompose above 900 K and was completely decomposed by the time 1300 K was reached. In the initial decomposition, the principal products were cyclopentadiene, benzene, propyne, and  $\text{C}_4\text{H}_x$ . At high temperatures, the cyclopentadiene decomposed as well, and the principal species observed were benzene, acetylene, and ethylene. From the combination of electron impact (EI) and chemical ionization (CI) mass spectra, it was confirmed that the  $\text{C}_6$  product observed was benzene, with few if any other  $\text{C}_6\text{H}_x$  products. Similarly, the  $\text{C}_5$  product was cyclopentadiene, with no cyclopentene or other  $\text{C}_5\text{H}_x$  products. The observed product distribution was inconsistent with both equilibrium speciation and predictions of existing JP-10 decomposition kinetic models.

Thermal cracking of JP-10 was studied in a batch reactor at different pressures [107]. The reactor effluent was quenched and collected at room temperature and atmospheric pressure. The gaseous and liquid components were quantitatively determined by GC and GC/MS. The conversion of JP-10 proceeded relatively slow at atmospheric pressure but increased under pressure. With an increase of the pressure,

the relative content of ethene or propene decreased and that of methane, ethane, or propane increased simultaneously. In the liquid products, cyclopentane, cyclopentene, 1,3-cyclopentadiene, and *cis*-bicyclo[3.3.0]oct-2-ene were found to be the major components. Substituted cyclopentene, benzene, toluene, and naphthalene were also observed at high pressures and temperatures. A probable mechanism for the thermal cracking of JP-10 was proposed to explain the product distribution. The process of isomerization might be dominating for liquid product formation during the thermal cracking under elevated pressures.

Molecular dynamics (MD) simulations using the ReaxFF reactive force field method were carried out to investigate the initiation mechanisms and kinetics associated with the pyrolysis of JP-10 (*exo*-tricyclo[5.2.1.0<sup>2,6</sup>]decane) [108]. It was found that the primary decomposition reactions involve either (1) dissociation of ethylene from JP-10, resulting in the formation of a C<sub>8</sub> hydrocarbon intermediate, or (2) the production of two C<sub>5</sub> hydrocarbons. ReaxFF MD calculations gave good agreement with experiments for the product distribution as a function of temperature. On the basis of the rate of consumption of JP-10, an activation energy of 244 kJ/mol (58.4 kcal/mol) for the thermal decomposition of this material was calculated, which was consistent with a strain-facilitated C—C bond cleavage mechanism in JP-10. This compared well with the experimental value of 261 kJ/mol (62.4 kcal/mol).

JP-10 pyrolysis was performed in a continuous flow tubular reactor near atmospheric pressure in the temperature range of 930–1080 K, a conversion range of 4–94%, and two dilution levels of 7 and 10 mol-% JP-10 in nitrogen [109]. Identification and quantification of the pyrolysis products of JP-10 were done by online two-dimensional GC with a time-of-flight MS and a flame ionization detector. JP-10 started to react at 930 K and was fully converted by the time it reached 1080 K. Among the more than 70 species up to C<sub>14</sub>H<sub>10</sub> that were identified and quantified, tricyclo[5.2.1.0<sup>2,6</sup>]dec-4-ene was identified for the first time, indicating the importance of bimolecular H-abstraction reactions in the consumption of JP-10. Critical assessment of the experimental data with the JP-10 combustion model developed by Magoon et al. in 2012 [110] showed that the model predictions of JP-10 agreed reasonably well. The new and highly detailed experimental data helped in understanding the thermal decomposition chemistry of JP-10 and can be used to validate future kinetic models of JP-10 pyrolysis.

Shock tube experiments and kinetic modeling efforts on the pyrolysis and combustion of JP-10 were performed at 6–8 atm using 2000 ppm of JP-10 in air over a temperature range of 1000–1600 K for pyrolysis and oxidation equivalence ratios from 0.14 to 1.0 [111]. GC/MS was used to identify and quantify the products within the shocked samples, enabling the tracking of product yield dependence on equivalence ratio as well as identifying several new intermediates that form during JP-10s decomposition. A detailed, comprehensive model of JP-10 combustion and pyrolysis kinetics was constructed with the help of RMG, an open-source Reaction

Mechanism Generation software package. The resulting model, which included 691 species reacting in 15518 reactions, was extensively validated against the shock tube experimental dataset as well as newly published flow tube pyrolysis data from [109, 112]. .. Most of the important rate coefficients were computed using quantum chemistry. The model succeeded in identifying all major pyrolysis and combustion products and captured key trends in the product distribution. Simulated ignition delays agreed within a factor of 4 with most experimental ignition delay data gathered from literature. The presented experimental work and modeling efforts yielded new insights on JP-10s complex decomposition and oxidation chemistry, and identified key pathways towards aromatics formation.

Two sets of experiments were performed to examine the high-temperature pyrolysis of tricyclo[5.2.1.0<sup>2,6</sup>]decane (JP-10) in high-temperature reactors over a temperature range of 1100–1600 K in the Advanced Light Source (ALS), and a temperature range of 927 to 1083 K in the National Synchrotron Radiation Laboratory (NSRL), with residence times of a few tens of microseconds (ALS) to typically 144 ms (NSRL) [113]. The products were identified *in situ* in supersonic molecular beams via single photon vacuum ultraviolet photoionization coupled with mass spectroscopic detection in a reflectron time-of-flight mass spectrometer. These studies were designed to probe the initial (ALS) and also higher order reaction products (NSRL) formed in the decomposition of JP-10, including free radicals and thermally labile closed-shell species. Altogether 43 reaction products were detected and quantified including C<sub>1</sub>–C<sub>4</sub> alkenes, dienes, C<sub>3</sub>–C<sub>4</sub> cumulenes, alkynes, enynes, diynes, cycloalkenes, cyclodienes, aromatic molecules, and most importantly, free radicals such as ethyl, allyl, and methyl produced at shorter residence times. At longer residence times, the predominant fragments were molecular hydrogen, ethylene, propene, cyclopentadiene, cyclopentene, fulvene, and benzene. Accompanied by electronic structure calculations, the initial JP-10 decomposition via C–H bond cleavages resulting in the formation of the initial six C<sub>10</sub>H<sub>15</sub> radicals was found to explain the formation of all products detected in both sets of experiments. These radicals were not stable under the experimental conditions and further decomposed via C–C bond  $\beta$ -scission processes. These pathways resulted in ring opening in the initial tricyclic carbon skeletons of JP-10. Intermediates accessed after the first  $\beta$ -scission can further isomerize or dissociate. Complex PAH products in the NURLS experiment (naphthalene, acenaphthylene, biphenyl) are likely formed via molecular growth reactions at longer residence times.

A multi-wavelength, multi-species laser was used to study the pyrolysis of JP-10 fuel [114]. Increasingly sophisticated multi-wavelength approaches were used to measure the species resulting from JP-10 pyrolysis in a shock tube at 2.7 atm near 1330 K. Laser absorption measurements in the far-IR region produced species time histories for ethylene and cyclopentadiene. Measurements of methane time histories were made in the mid-IR region.

Cetyl-hyperbranched polyethyleneimine (CHPEI) synthesized from the modification of hyperbranched polyethyleneimine (HPEI) with a lipophilic alkyl chain was used as a novel macroinitiator to accelerate the thermal cracking of hydrocarbon fuels and improve the cooling capacity for aircraft heat exchangers [115]. The pyrolysis performances under supercritical conditions (4.0 MPa and 873–973 K = 600–700 °C) of JP-10 with CHPEI and the monomer triethylamine were compared in an electrically heated alloy tube. Both types of initiators with C–N bonds can promote the thermal cracking of JP-10, while CHPEI with a large molecular weight showed a crack-promoting effect similar to that of triethylamine with adding only one-tenth of the amount of the latter. As a typical example, the addition of 0.20 mass-% CHPEI increased the conversion rate of JP-10 from 16.4 to 33.9%, and the corresponding heat sink was improved from 1.96 to 2.18 MJ/kg at 948 K (675 °C). On the basis of investigations on the intermediate species from different decomposition pathways of JP-10, it was shown that CHPEI accelerates the thermal cracking of JP-10 by generating free radicals to participate in the H-abstraction reaction of JP-10.

#### 7.4.3.1 Catalyzed Decomposition of JP-10

Catalytic cracking of JP-10 and other hydrocarbons can lower the operating temperature of endothermic cooling jackets on hypersonic missiles and create more readily combustible fuel mixtures. Catalytic cracking of JP-10 is an important technology to improve its cooling or heat sink capacity. The following references to catalytic cracking of JP-10 are arranged in chronological order.

The decomposition of JP-10 through thermal and catalytic cracking at elevated temperatures using a bench-top reactor system with industrial zeolite catalysts was studied in a system that had the capability to vaporize liquid fuel at precise flowrates while maintaining the flow path at elevated temperatures and pressures for extended periods of time [116, 117]. A gas chromatograph with a capillary column and flame ionization detector, connected to the reactor output, was used to analyze the reaction products. The conversion rate and product compositions were determined as functions of the fuel metering rate, reactor temperature, system backpressure, and zeolite type. An additional study was carried out to evaluate the feasibility of using pre-mixed rich combustion to partially oxidize JP-10. A mixture of partially oxidized products was initially obtained by rich combustion in air/JP-10 mixtures for equivalence ratios between 1 and 5. Following the first burn, air was added to the products, creating an equivalent stoichiometric mixture. A second burn was then carried out. Pressure histories and schlieren video images were recorded for both burns. The results were analyzed by comparing the peak and final pressures to computed thermodynamic predictions.

Catalytic pre-cracking of JP-10 could provide a more easily detonated mixture of light olefin products for pulse detonation engines. A mixture of mostly light hydrocarbons has the added benefit of being less prone to coking than a product mixture

heavy in aromatics. Several heterogeneous catalytic cracking tests of JP-10 have been done using a benchtop tubular reactor and the products were analyzed with GC/MS and GC [118]. Two forms of nanocrystalline zeolites and three forms of silico-alumino-phosphates successfully catalyzed the thermal cracking of JP-10. Both zeolite catalysts converted over 90% of JP-10 within a ~3-s residence time into a mixture of hydrocarbon products consisting mainly of  $C_4$  and lower chain hydrocarbons ( $C_3$  to  $C_1$ ).

Thermal breakdown and oxidation of JP-10 in the presence of nanoparticulate  $CeO_2$  and  $Fe_2O_3$  was studied in a small alumina flow-tube reactor with dwell time durations around 1 ms [119]. Decomposition products were analyzed by an *in situ* mass spectrometer. In the absence of any oxidizer, JP-10 pyrolyzed at temperatures above ~900 K to a variety of hydrocarbon fragments. In the absence of  $O_2$ , both  $CeO_2$  and  $Fe_2O_3$  oxidized JP-10 efficiently, with decomposition onset temperatures up to 300 K lower than in a clean alumina flow tube under identical flow conditions and substantial conversion to products such as water,  $CO_2$ , CO, and formaldehyde. Under such non-catalytic conditions, the  $CeO_2$  or  $Fe_2O_3$  was reduced and deactivated by the reaction with JP-10. Decomposition of JP-10 in the presence of stoichiometric amounts of  $O_2$  was also studied, with and without  $CeO_2$  present. In absence of  $CeO_2$ , some oxidation products were observed; however, the rate-limiting step appeared to be pyrolysis of JP-10, and pyrolysis products dominated for temperatures up to 1200 K. When both  $O_2$  and  $CeO_2$  were present, oxidation was clearly catalytic, i.e., oxidation was initiated by the reaction of JP-10 with  $CeO_2$ , which is then reoxidized by  $O_2$ .

JP-10 has significant sensible heat sink capacities and may undergo endothermic chemical cracking for hypersonic aircraft applications without the problems associated with other endothermic fuels. Chemical initiators may accelerate the rate of cracking reactions and reduce the required temperatures in a hypersonic aircraft heat exchanger/reactor. On the other hand, with the addition of an initiator some other basic properties of JP-10 may change, such as volatility, which is directly related with ignition performance and combustion problems. Tributylamine (TBA) can be used as an effective initiator. TBA and JP-10 blended fuel were evaluated as a potential fuel for hypersonic aircraft [120]. The bubble-point vapor pressures and equilibrium temperatures for mixtures of JP-10 and TBA with different mass fractions were measured by comparative ebulliometry with inclined ebulliometers. Vapor pressures and equilibrium temperatures were correlated by Antoine's equation with satisfactory precision. Bubble-point lines of pressure versus composition at different temperatures and temperature versus composition at different pressures were obtained. The mixtures exhibited positive deviations from Raoult's law. It was shown that the addition of TBA does not have a distinct effect on the vapor pressure and the phase equilibrium behavior of JP-10.

Compared to thermal cracking of JP-10, the conversion ratio of catalytic cracking JP-10 over ZSM-5 molecular sieves in the temperature range from 773 to 923 K (500 to 650°C) is substantially enhanced [121]. The predominant products of the catalytic

cracking were methane, ethane, ethylene, propane, propylene, benzene, and benzenoid hydrocarbons. It was found that indene and naphthalene, which have negative effects on the combustion quality, were produced because of a hydrogen transfer reaction at high temperatures. High conversion ratio and low content of aromatics could not be obtained at the same time. A reaction mechanism of the catalytic cracking of JP-10 was proposed based on both the measured product composition and quantum mechanical calculation.

A pseudohomogeneous method of catalytic decomposition of JP-10 was developed using well-dispersed nickel nanoparticles [122]. Compared with thermal decomposition, catalytic reaction of JP-10 on nickel nanoparticles exhibited remarkably enhanced rates of conversion. The content of hydrogen and alkene of catalytic reaction products was higher than that of thermal decomposition at temperatures from 813 to 873 K (540 to 600 °C).

Quasi-homogeneous catalytic cracking of hydrocarbon fuels using dispersible zeolite is an effective way to improve their cooling capacity for future hypersonic aircraft. Hydrocarbon dispersible beta nanozeolites were hydrothermally synthesized [123]. IR and TGA analyses indicated that these zeolites have more organic groups anchored on their surface than other zeolites, leading to a higher external surface area and better dispersibility in JP-10. Experiments with the quasi-homogeneous catalytic cracking of JP-10 were conducted in an electrically heated tube in the laboratory under a pressure of 4 MPa. The heat sink capacity of JP-10 reached 2800 kJ/g at 973 K (700 °C) using 100 ppm zeolite as a quasi-homogeneous additive, achieving high catalytic cracking conversion of 63% and high alkenes selectivity (57% in the gaseous products), compared with both thermal cracking or catalytic cracking of JP-10 with other zeolites. The good catalytic performance may be attributed to the high external surface area and good dispersibility in JP-10.

The catalytic cracking of JP-10 at 773 K (500 °C) with a mass hourly space velocity of  $22.56 \text{ h}^{-1}$  over nanosheets gave a conversion of 45%, which was 77% higher than that obtained over a conventional zeolite catalyst (CZ-25, 25%), and the deactivation rate was relatively low (only two-thirds that of CZ-25) [124]. Characterization of the catalysts using ammonia temperature-programmed desorption measurements and FTIR spectroscopy indicated that the better catalytic performance may be attributed to more Brønsted acid sites on the external surface, which is favorable for the larger molecules (like JP-10), and higher accessibility of acid sites in the micropores of nanosheets due to the shorter diffusion path (less than 2.0 nm). The enhanced diffusion of JP-10 over nanosheets also leads to high olefin yields, and better coking tolerance through prevention of secondary reactions.

The cracking of JP-10 with and without the hydrogen form of Y-type zeolite (H-Y zeolite) as catalysts was determined over a wide range of operating conditions relevant to endothermic fuels using both a fixed bed reactor and a microflow tube reactor [125]. The predominant reaction during supercritical pyrolytic cracking was carbon-carbon

bond cleavage to form the primary products of cyclopentadiene and cyclopentene. In contrast, the predominant reaction during supercritical catalytic cracking was the formation of secondary products such as naphthalene and substituted indenenes from primary products via molecular growth reactions. Turnover frequencies for the cracking of JP-10 over H-Y zeolite under supercritical conditions were obtained and used to determine the apparent activation energy of JP-10 cracking over H-Y ( $186 \pm 9$  kJ/mol). Atmospheric microflow tube reactor results were obtained to better understand the flow residence time and transport effects, and they showed that catalytic cracking slightly decreased the endothermic cooling capacity as compared to pyrolytic cracking at similar levels of conversion. However, at similar levels of conversion, the addition of a catalyst reduced cracking temperatures by 210 K.

Cetyl-hyperbranched polyethyleneimine (CHPEI) synthesized from the modification of hyperbranched polyethyleneimine with a lipophilic alkyl chain was used as a macroinitiator to accelerate the thermal cracking of hydrocarbon fuels and improve the cooling capacity for aircraft heat exchangers [115]. The rate of pyrolysis under supercritical conditions (4.0 MPa, and 873–973 K = 600–700 °C) of JP-10 (*exo*-tricyclo[5.2.1.0<sup>2,6</sup>]decane) with CHPEI and the monomer triethylamine were compared in an electrically heated alloy tube. Both types of initiators with C–N bonds can promote the thermal cracking of JP-10, while CHPEI with a large molecular weight showed a similar crack-promoting effect to that of triethylamine with adding only one-tenth of the amount of the latter. As a typical example, the addition of 0.20 mass-% CHPEI increased the conversion rate of JP-10 from 16.4 to 33.9%, and the corresponding heat sink was improved from 1.96 to 2.18 MJ/kg at 948 K (675 °C). CHPEI accelerated the thermal cracking of JP-10 by generating free radicals to participate in the H-abstraction reaction of JP-10.

#### 7.4.3.2 Coke Deposition During JP-10 Decomposition

The fouling of JP-10 on the inner surface of CRES-316L tubes was investigated at wall temperatures from 533 to 623 K (260 to 350 °C) and at 3.84 MPa with a flow rate of 0.5 mL/min for 24 h [126]. The fouling of JP-10 was influenced by wall temperature, fuel temperature, and the type of metal surface. The average values of coke deposits were measured to be between 7.52 and 10.67  $\mu\text{g}/\text{cm}^2$  by a carbon burn-off method, and the maximum values of local coke deposits and average values of coke deposits increased with the wall temperature. At 573–623 K (300–350 °C) the locations of peak deposition shifted upstream as the wall temperature increased. The nature and morphology of deposits were characterized by field emission scanning electron microscopy and temperature programmed oxidation profiles, and the deposits of JP-10 were mainly in the form of amorphous carbon. Structurally more ordered deposits were also found, and it could be caused by the catalysis of iron and nickel in metal surfaces.

Coking of three model compounds for hydrocarbon fuels: *n*-heptane, cyclohexane, and tricyclo[5.2.1.0<sup>2,6</sup>]decane (JP-10), during their thermal cracking processes un-

der supercritical conditions (873 K, 4.1 MPa) was investigated and the compositions of the thermal cracking products were analyzed by GC-MS [127]. The morphology and microstructures of the cokes were characterized by SEM, TEM, DSC, and XRD. The results showed that chemical structures play important roles in the thermal stability and coking property of the fuels. The thermal cracking conversion of *n*-heptane was the highest, and the coke yield of JP-10 was highest under the same conditions. It was observed that the morphologies of the cokes produced from the thermal cracking of three fuels were quite different. Cokes from *n*-heptane, cyclohexane, and JP-10 were in the forms of carbon nanofilaments, carbon nanotubes, and irregular carbon particles, respectively.

#### 7.4.3.3 Computational Chemistry Studies of JP-10 Decomposition

Computational chemistry with quantum chemical calculations was used to identify the weakest chemical bonds in the *exo*-tetrahydrodicyclopentadiene (JP-10) molecule where bond breakage was most likely to occur first on heating. Density functional theory (DFT) calculations have been carried out to investigate the thermal cracking pathways of JP-10 [128]. Several thermal cracking mechanisms were proposed, as reported previously [107]. Using DFT calculations, the potential energy profiles of the possible thermal cracking pathways for all of the diradicals obtained from homolytic C—C bond cleavage of JP-10 were derived. The predicted products of the different thermal cracking pathways were in good agreement with previous experimental observations.

A detailed kinetic model for the thermal decomposition of JP-10 was constructed using a combination of automated mechanism generation techniques and *ab initio* calculations [112]. Rate coefficients for important unimolecular initiation routes of *exo*-THDCPD were calculated using the multi-reference method CAS-PT2, while rate coefficients for the various primary decompositions of the *exo*-THDCPD-derived monoradicals were obtained using CBS-QB3. Rate-of-production analysis showed the importance of four dominating JP-10 decomposition channels. The model predictions agreed well with five independent experimental data sets for JP-10 pyrolysis that covered a wide range of operating conditions ( $T = 300 - 1500$  K,  $P = 300$  Pa to  $1.7 \times 10^5$  Pa, dilution = 0.7–100 mol-% JP-10, conversion = 0–100%) without any adjustment of the model parameters. A significant part of the model comprised secondary conversion routes to aromatic and polyaromatic hydrocarbons and could, thus, be used to assess the tendency for deposit formation in fuel-rich zones of endothermic fuel applications.

The hybrid chemistry (HyChem) approach has been proposed previously for combustion chemistry modeling of real, liquid fuels of a distillate origin. The applicability of the HyChem approach was tested for single-component fuels using JP10 as the model fuel [129]. The method remained the same: an experimentally constrained, lumped single-fuel model describing the kinetics of fuel pyrolysis was combined with a detailed foundational fuel chemistry model. Due to the multi-ring molecular structure of JP10, the pyrolysis products were found to be somewhat different from those

of conventional jet fuels. The lumped reactions were therefore modified to accommodate the fuel-specific pyrolysis products. The resulting model showed generally good agreement with experimental data, which suggested that the HyChem approach is also applicable for developing combustion reaction kinetic models for single-component fuels.

Theoretical calculations of the rate constants and product branching ratios in the pyrolysis of *exo*-tetrahydrodicyclopentadiene (JP-10) and its initial decomposition products at combustion-relevant pressures and temperatures were performed and compared to the experimental results from the reported molecular beam photoionization mass spectrometry study of the pyrolysis of JP-10 [113, 130]. The results allowed a quantitative assessment of the decomposition mechanisms of JP-10 by a direct comparison with the nascent product distribution, including radicals and thermally labile closed-shell species, detected in the short-residence-time molecular beam photoionization mass spectrometry experiment. In accord with the experimental data, the major products predicted by the theoretical modeling included methyl radical ( $\bullet\text{CH}_3$ ), acetylene ( $\text{C}_2\text{H}_2$ ), vinyl radical ( $\bullet\text{C}_2\text{H}_3$ ), ethyl radical ( $\bullet\text{C}_2\text{H}_5$ ), ethylene ( $\text{C}_2\text{H}_4$ ), allyl radical ( $\bullet\text{C}_3\text{H}_5$ ), 1,3-butadiene ( $\text{C}_4\text{H}_6$ ), cyclopentadienyl radical ( $\bullet\text{C}_5\text{H}_5$ ), cyclopentadiene ( $\text{C}_5\text{H}_6$ ), cyclopentenyl radical ( $\bullet\text{C}_5\text{H}_7$ ), cyclopentene ( $\text{C}_5\text{H}_8$ ), fulvene ( $\text{C}_6\text{H}_6$ ), benzene ( $\text{C}_6\text{H}_6$ ), toluene ( $\text{C}_7\text{H}_8$ ), and 5-methylene-1,3-cyclohexadiene ( $\text{C}_7\text{H}_8$ ). Ethylene, allyl radical, cyclopentadiene, and cyclopentenyl radical were significant products at all combustion-relevant conditions, whereas the relative yields of the other products depended on temperature. The most significant temperature trends predicted were increasing yields of the  $\text{C}_2$  and  $\text{C}_4$  species and decreasing yields of the  $\text{C}_1$ ,  $\text{C}_6$ , and  $\text{C}_7$  groups with increasing temperature. The calculated pressure effect on the rate constant for the decomposition of JP-10 via initial C—H bond cleavages became significant at temperatures above 1500 K. The initially produced radicals will react away to form closed-shell molecules, such as ethylene, propene, cyclopentadiene, cyclopentene, fulvene, and benzene, which were observed as the predominant fragments in the long-residence-time experiment. The calculated rate constants and product branching ratios should prove useful to improve the existing kinetic models for the JP-10 pyrolysis.

Functionalized graphene sheets (FGS) have proven to be an effective nanoparticle additive to enhance decomposition of jet fuels. The reactive force field (ReaxFF) molecular dynamics (MD) simulation was used to investigate the initiation mechanisms of JP-10 pyrolysis and oxidation with FGS in comparison with normal JP-10 reactions [131]. ReaxFF calculations were performed to study the transition state and energy barrier for key initiation reactions in order to reveal the catalytic effect of FGS on JP-10 pyrolysis and oxidation. The results showed that both pyrolysis and oxidation of JP-10 can be advanced and enhanced in the presence of FGS, leading to earlier decomposition of JP-10 at a lower temperature and a faster reaction rate. It was found that the OH functional group on the FGS not only advanced the initiation of JP-10 but also

participated in various intermediate reactions to further enhance the pyrolysis and oxidation of JP-10. The dehydrogenation of JP-10 without FGS was only observed at very high temperatures. Deeper insight into the enhancement resulting from the FGS was provided through the analysis of the results of transition state and energy barrier for key initiation reactions. It was found that JP-10 decomposition initiated by OH or H on the FGS occurred at a lower energy barrier than unimolecular decomposition or through reaction with O<sub>2</sub>, thereby changing and enhancing the JP-10 initiation.

#### 7.4.4 Ignition of JP-10 in Air

Although the combustion of JP-10 in air is planned to be discussed in a future set of the *Encyclopedia of Rocket Propellants*, some chemical reactions that may lead to ignition of JP-10 vapors in air, an important step in the use of JP-10 in propulsion systems, are already discussed here. Ignition delay times and OH concentration time histories for JP-10/O<sub>2</sub>/Ar mixtures have been measured behind reflected shock waves over the temperature range of 1200–1700 K, pressure range of 1–9 atm, fuel concentrations of 0.2 and 0.4%, and stoichiometric ratios of  $\Phi = 0.5, 1.0$  and 2.0 [132]. Fuel concentrations were measured in the shock tube using laser absorption at 3.39  $\mu\text{m}$ , ignition times were determined using CH emission, and OH concentration histories were inferred from narrow-linewidth continuous wave (CW) laser absorption measurements near 306 nm. The laser measurements also revealed evidence for a long-lived JP-10 decomposition product with strong absorption near 306 nm. A kinetic model for JP-10 oxidation was developed using global decomposition reactions proposed by others. This modeling gave good agreement with the ignition times at higher pressures, and sensitivity studies using this model indicated the possible important role of C<sub>2</sub> chemistry in JP-10 decomposition.

A pressure-dependent, detailed chemical kinetic mechanism that describes the combustion of JP-10 was developed through the use of dynamic trajectory analysis to identify potential reaction pathways, *ab initio* chemistry calculations to determine thermochemical properties and kinetic rates, and *ab initio* chemistry and group additivity theory to calculate transport properties [133]. A comparison of predicted and measured values for ignition delay and species profiles from the literature showed good agreement. In addition, new data for species profiles were developed.

#### 7.4.5 Electron Impact Ionization of JP-10

The ionization of JP-10 (C<sub>10</sub>H<sub>16</sub>, *exo*-tricyclo[5.2.1.0<sup>2,6</sup>]decane) by electron impact has been studied using Fourier transform mass spectrometry [134]. This is similar to what happens to JP-10 vapors in the inlet section of a mass spectrometer. Absolute total and partial ionization cross-sections have been measured as functions of the electron energy in the range of 10–200 eV. The major channel of parent ion fragmentation at low energies (<27 eV) produced C<sub>9</sub>H<sub>13</sub><sup>+</sup>, and at higher energies, C<sub>5</sub>H<sub>7</sub><sup>+</sup>. Several possible fragmentation mechanisms were proposed.

The plasma cracking of *exo*-tetrahydrodicyclopentadiene (JP-10) ( $C_{10}H_{16}$ ) was investigated using a quadrupole mass spectrometer [135, 136]. The relative densities of the JP-10 molecule and its principal decomposition products, including  $H_2$ , were determined for varying radiofrequency (rf) powers in the range of 3–30 W, using the measured ion intensities combined with ionization cross section data from the literature. The extent of the cracking of JP-10 and the formation of  $H_2$  as functions of the intensity of the applied rf power were discussed.

#### 7.4.6 Analysis of JP-10

The components of four samples of JP-10 were analyzed by GC/MS [137]. The purity of JP-10 fuels was measured with an external standard method. Results showed that JP-10 contains not only the main component *exo*-tetrahydrodicyclopentadiene, but also decahydronaphthalene, *endo*-tetrahydrodicyclopentadiene, adamantane, and their methylated homologues. The suitable concentration range for the external standard method to measure the purity of JP-10 is 0.5–20 mg/mL. This method is supposed to be reliable, accurate, and can be used for determining the purity of JP-10.

### 7.5 Materials Compatibility of JP-10

The fuel system icing inhibitor (FSII) in JP-10 fuel was found to corrode aluminum components in missile fuel systems during long-term storage under an anhydrous nitrogen atmosphere [138–140]. Previous investigations into fuel-system corrosion had used extreme conditions such as high FSII concentration or temperature to accelerate corrosion. Electrochemical impedance spectroscopy (EIS) was used to determine the corrosion rate on Al 2024, Al 6061, Al A357, and Al 7075 as a function of additive type and concentration under conditions similar to those found in actual use.

To explore the possibility of using advanced surface engineering techniques (ASETs) to solve the friction and wear problems caused by the poor lubricity of pure, low-viscosity aviation fuel JP-10, polished M50 bearing steel sample surfaces were treated with nitrogen ion implantation, TiAlN coating deposition, and Ta coating deposition followed by high current pulsed electron beam (HCPEB) irradiation, respectively [141]. Boundary tribological behaviors of these ASET-treated and untreated steel samples sliding in pure JP-10 against a  $Si_3N_4$  ball (ball-on-disc model) were investigated under 2.0 GPa in the atmosphere and the friction tests indicated that significant reductions, although to different extents, in friction and wear were achieved by these modified surfaces. Simultaneously considering the tribological performance and potential pollution caused by wear debris to JP-10, HCPEB-treated Ta coating with a lowest average friction coefficient of 0.11 and a specific wear rate of around zero was the best to offset the inadequate lubricity of JP-10 by itself under laboratory conditions.

## 7.6 Toxicity of JP-10

Pregnant ICR mice were given oral doses of 0.2, 0.4, 0.6, and 0.8 mL/kg of JP-10 on days 6 through 9 of gestation [142]. No significant differences were found between controls and experimental groups in mean implants/female, mean viable fetuses/litter, mean resorptions/litter, frequency of resorptions, frequency of soft tissue anomalies, and frequency of skeletal anomalies. Mean fetal weight was significantly heavier in the 0.2 and 0.4 mL/kg groups. This effect is difficult to explain when the 0.6 and 0.8 mL/kg groups showed no increase in fetal weight.

The effect of JP-10, the major component of cruise missile fuel, on the development of embryonic rats was evaluated. Pregnant females were exposed via inhalation to 600 ppm or orally dosed with 250, 500, or 1000 mg JP-10/kg on gestation days 6–15 [143, 144]. In a separate experiment, both fetal and maternal blood levels of JP-10 were monitored during an inhalation exposure. Moderate signs of toxicity including tremors and convulsions were observed in the pregnant females receiving the higher doses. JP-10 was not selectively embryotoxic in the rat when administered by gavage or inhalation. Blood levels of JP-10 in the fetuses was about one half the maternal blood levels at steady state.

## 7.7 Fire Hazard Properties of JP-10

### 7.7.1 Limits of Flammability of JP-10

The flammability limits of air/JP-10 vapor mixtures were near those of gaseous air/*n*-decane mixtures. However, the maximum explosion pressure and the maximum rate of pressure rise of air/JP-10 vapor mixtures were much higher than those of gaseous air/*n*-decane mixtures.

### 7.7.2 Autoignition Temperature of JP-10 in Air

The autoignition temperature of JP-10 in air is 518 K = 474 °F [6].

### 7.7.3 Flash Point of JP-10

The TAG flash point of JP-10 is 323.6 K (50.5 °C). The Military Specification MIL-DTL-87107E requires that the flash point of JP-10 must be above 327.5 K = 54.4 °C = 130 °F.

### 7.7.4 Explosion of Air/JP-10 Vapor Mixtures

Additional discussion of explosions of air/JP-10 vapor mixtures will be provided in a future set of *Encyclopedia of Rocket Propellants*. An examination of the flammability of JP-10 included maximum explosion pressure, maximum rate of pressure rise,

and limiting flammability concentrations [145]. Through a series of experiments, the influences of the concentration of gaseous JP-10 in air on the explosion pressure and on the rate of explosion pressure rise have been analyzed. The explosion pressure of gaseous air/JP-10 mixtures reached their highest values at a concentration of 1.88%. The variation trends in the explosion pressure and the rate of pressure rise of gaseous air/JP-10 mixtures with vol.-% appeared similar. When the vol.-% of gaseous JP-10 was in the range 0.5–1.8%, the explosion pressure and the rate of pressure rise for gaseous air/JP-10 mixtures increased with the vol.-%, while in the range 1.8–5% these parameters decreased with the vol.-%. The flammability limits of air/JP-10 vapor mixtures were near those of gaseous air/*n*-decane mixtures. However, the maximum explosion pressure and the maximum rate of pressure rise of air/JP-10 vapor mixtures were much higher than those of gaseous air/*n*-decane mixtures.

### 7.7.5 Explosion of Air/JP-10 Aerosol Mixtures

The flammable range for JP-10 vapor in air is 0.7–5.3 vol.-% at standard temperature and pressure (STP), but the flammable range of JP-10 aerosol sprays in air is much wider. The explosion parameters of vapor/liquid two-phase JP-10/air mixtures were determined in a 20-L cylindrical vessel for two sets of JP-10/air mixtures at different fuel concentrations, with mean aerosol droplet diameters of 20 and 35  $\mu\text{m}$  [146]. The explosion temperature, pressure and lower flammability limits were measured and analyzed. The peak overpressures,  $\sim 0.85$  MPa, for 20 or 35  $\mu\text{m}$  diameter droplets were very similar and occurred at a vapor equivalent of 1.6 vol.-% ( $600 \text{ g/m}^3$ ) JP-10, just a little on the fuel-rich side of the stoichiometric composition (1.48 vol.-%), within 100 ms from ignition. The pressure rise rate for 35- $\mu\text{m}$  droplets maxed at 90 MPa/s. This information is of interest for the design of air/JP-10 pulse detonation engines.

## 7.8 Fuel Mixtures with JP-10

Additions of cycloalkanes enhance the endothermic fuel capabilities of JP-10 [147]. The bubble-point vapor pressure, density, and viscosity for binary mixtures of tricyclo[5.2.1.0<sup>2,6</sup>]decane (JP-10) with methylcyclohexane (MCH) were measured at several temperatures [148]. The correlation between vapor pressures and equilibrium temperatures of each mixture was performed and the Antoine equation parameters were given correspondingly. The experimental vapor liquid equilibrium data were correlated with the Wilson model. From the density and viscosity data, excess volume and viscosity deviation,  $\Delta\eta$ , for the binary mixtures were calculated and fitted with the Redlich–Kister equation. The viscosities were correlated with several semi-empirical equations. The excess molar volumes and the viscosity deviations were negative over the entire composition range.

Densities, viscosities, and refractive indices were measured for the binary system of tricyclo[5.2.1.0<sup>2,6</sup>]decane with cyclohexane, methylcyclohexane, ethylcyclohexane, butylcyclohexane, or 1,2,4-trimethylcyclohexane at temperatures from 293 to 318 K and at atmospheric pressure with  $p = 0.1$  MPa [149]. The excess molar volumes ( $V_mE$ ), the viscosity deviations ( $\Delta\eta$ ), and the refractive index deviations ( $\Delta nD$ ) were then calculated. The changes of  $V_mE$  and  $\Delta\eta$  with the composition were fitted to the Redlich–Kister equation. The values of density, viscosity, and refractive index increase continuously with the increase of mol fraction of tricyclo[5.2.1.0<sup>2,6</sup>]decane and decrease with the rise of temperature. The  $V_mE$  and  $\Delta\eta$  are all negative over the whole composition range for these five binary systems which is typical for molecular interactions in binary systems.

The fundamental physical properties including density, viscosity, refractive index, and relative permittivity have been measured for binary mixtures of *exo*-tetrahydrodicyclopentadiene (JP-10) with four octane isomers (*n*-octane, 3-methylheptane, 2,4-dimethylhexane and 2,2,4-trimethylpentane) over the whole composition range 293–313 K and at atmospheric pressure  $p = 0.1$  MPa [150]. The values of excess molar volume, viscosity deviation ( $\Delta\eta$ ), refractive index deviation ( $\Delta nD$ ), and relative permittivity deviation ( $\Delta\epsilon_r$ ) were then calculated. All of the values of  $V_mE$  and  $\Delta\eta$  were observed to be negative, while those of  $\Delta nD$  and  $\Delta\epsilon_r$  were close to zero. The negative values of  $V_mE$  and  $\Delta\eta$  are conducive to high-density and low flow-resistance of fuels, which is favorable for advanced hydrocarbon fuels.

Density, viscosity, and vapor pressure of binary mixtures of *exo*-tetrahydrodicyclopentadiene (JP-10) with isopropyl ether were measured between 293 and 313 K over the entire composition range [151]. Densities and viscosities of a 50/50 by volume mixture of JP-10 and a turpentine dimer fuel have been measured in the compressed-liquid state from 270 to 470 K, 0.5 to 45 MPa, and at ambient pressure from 263.15 to 373.15 K [152]. Ambient pressure dynamic viscosity was measured over the same temperature range. Results of the mixture measurements were compared with previously measured densities of the individual components, turpentine dimer fuel and JP-10.

The heat of combustion of JP-10 or quadricyclane can be increased by dissolving acetylene in the fuel. The solubility of acetylene in JP-10 or quadricyclane can be enhanced by adding triethylamine [153]. The solubility of acetylene in JP-10 at 298 K and pressures up to 200 kPa was studied. The molar concentration of acetylene in JP-10 at a pressure of 100 kPa reached 0.60 mol-% prior to addition of the amine. The solubility of acetylene in the presence of triethylamine showed that such additives could increase significantly the solubility of acetylene in the fuel.

## 7.9 Applications of JP-10

### 7.9.1 Gelled JP-10

Like all kerosenes, JP-10 can be gelled and its heat of combustion can be increased by suspending metal powders in the gel. The high viscosity of the gel will prevent the heavier metal particles from settling during storage or high-g acceleration.

Surface-modified boron nanoparticles (NPs) were added to jet fuel JP-10 with tri-octylphosphine oxide as the stabilizer which inhibited particle contact and agglomeration [154]. After 6 weeks, a suspension with 12.7 mass-% boron nanoparticles was still completely dispersed in the fuel. Addition of 12.7 mass-% boron increased the density and volumetric energy from 0.93 g/mL and 39.4 MJ/L to 0.98 g/mL and 43.4 MJ/L, respectively. The suspension flowed freely like liquid fuel and had relatively low viscosity at low temperature.

JP-10 supramolecular gel propellants were prepared by dissolving the low-molecular mass gelator 1,1',1''-[(2,4,6-trioxo-1,3,5-triazinane-1,3,5-triyl)tris-(hexane-6,1-diyl)]tris(3-octadecyl-urea) (HDIT-18) in JP-10 [155]. The critical gelator concentration for JP-10 was as low as 0.0638 mass-%. The JP-10 supramolecular gel propellants exhibited high thermal stability. Scanning electron microscopy (SEM) studies revealed that the gelator molecules self-assembled into 1–3  $\mu\text{m}$  fibers in JP-10. Rheological studies showed that the JP-10 supramolecular gels were thixotropic and shear-thinning (for a shear rate range from 0.3 to 30  $\text{s}^{-1}$ ). The dynamic strain sweep test showed that the critical strain percentage of the gel materials was 1%.

### 7.9.2 Metallized JP-10

Nanofluid fuels were examined through theoretical and experimental methods. Theoretical calculations showed that aluminum is very effective in improving the volumetric specific impulse and density of JP-10 [156]. A surface-modification method was developed to stabilize Al nanoparticles in fuel, and oleic acid was the most effective coating agent. The surface modification inhibited the contact and agglomeration of nanoparticles and maintained them stably dispersed in fuel. With the addition of 30% Al, the density and volumetric energy of JP-10 was increased by 20 and 10%, respectively, and the fuel can flow freely. Combustion tests showed that the combustion efficiency of Al nanoparticles was higher than 95%, with density specific impulse of JP-10 being increased by 15% through the addition of 16% Al nanoparticles.

Nanosize aluminum (16 mass-%) was suspended in JP-10 and 2 mass-% of a surfactant was used to reduce the agglomeration of nanoparticles. Combustion of metalized fuel, as well as pure JP-10, was carried out in a small-scale combustor [157]. The oxygen-to-fuel ratios were set at 1.7, 1.8, and 1.9. The effect of water injection during combustion was also tested. The pressures at the combustion chamber and nozzle exit, along with the thrust, were measured during the combustion and intervals of true values of the specific impulse were presented. The results

showed that a 3 to 9% improvement in combustion efficiency was achieved with the JP-10-based slurry when compared to pure JP-10. However, the specific impulse could be increased only when the combustion-induced heat release was improved enough to overcome the two-phase loss. Depositions at different positions were collected after combustion for deep analysis by XRD, TGA, SEM, and laser light scattering. A relatively high oxidation rate of the aluminum was obtained in tests without water injection, and the solid particles were mainly spherical and 100–300 nm in size. In the tests with water injection, stable combustion and increased thrust were achieved, whereas the combustion efficiency and specific impulse were decreased and the size of the particles was increased due to the addition of water.

D-gluconic acetal supramolecular organic gelators can form gels with JP-10 [158]. Rheological measurements showed that G8 gel exhibited good mechanical strength at a concentration of 2 mass-%, while G18 gel had a remarkable yield stress. JP-10 gels showed thixotropy with high viscosity, especially for the G8-based gel, which had an instantaneous recovery ratio. The CGC (critical gelator concentration) of G8 was less than 0.1 mass-%. G18 can gel JP-10 at room temperature, which was the first example of room temperature gel propellant formed by a supramolecular gelator. Nano accelerants (Al, B) can be dispersed into the gel propellant system, which can be stable for months. The presence of 50 nm Al powder in G8-based gels can significantly increase its mechanical strength, yield stress, and viscosity, as well as thixotropy. Addition of nano-aluminum to JP-10 increased the heat of combustion and enhanced the combustion behavior in air [159].

## 8 Commercial Fuel Jet A

Commercial fuel Jet A is rarely used as a rocket propellant. Some of its properties are listed here only for comparison to some of the other kerosene fuels. Jet A specification fuel has been used in the United States since the 1950s, whereas Jet A-1 is the standard specification fuel used in the rest of the world other than the former Soviet Union states where TS-1 is the most common standard. Both Jet A and Jet A-1 have a flash point higher than 311 K (38 °C = 100 °F), with an autoignition temperature of 383 K (210 °C = 410 °F). Jet A is used as the fuel in the South Korean KSLV-II launch vehicle with LOX as the oxidizer.

### 8.1 Physical Properties of Jet A

Although this is primarily a book on rocket propellants, we include jet engine fuels here because in the early years, any kerosene—including blends similar to what is now designated Jet A—was used for rocket engine tests, mostly because it was readily available. There are numerous publications dealing with the properties of kerosene

Jet A fuel. The primary difference between Jet A and Jet A-1 is the lower freezing point of Jet A-1. Jet A freezes at 233 K ( $-40^{\circ}\text{C} = -40^{\circ}\text{F}$ ), whereas Jet A-1 freezes at 226 K ( $-47^{\circ}\text{C} = -53^{\circ}\text{F}$ ). Without going into details, we list a few references here which will be useful to our readers for future study [160]. A synthetic fuel, S-8, similar to JP-8, was derived from the Fischer–Tropsch process. Clearly, rocket propellants are not used as fuels for air-breathing commercial transport planes; however, as there is some overlap in the methods for evaluation of the thermal stability of these fuels that can be applied to both rocket fuels and jet engine fuels, they are included here.

## 8.2 Chemical Properties of Jet A

### 8.2.1 Composition of Jet A

The chemical composition of Jet A is essentially identical with that of JP-8, except that Jet A does not contain any of antioxidant and anticorrosive additives. The primary difference in chemical composition between Jet A and Jet A-1 is the mandatory addition of an anti-static additive to Jet A-1.

### 8.2.2 Surrogate Fuel Mixtures for Jet A

Because of the complexities involved in measuring and modeling the performance and properties of finished fuels, the fuel science community must often use surrogate mixtures as substitutes, especially in the absence of consensus standard mixtures. While surrogate mixtures are often formulated on the basis of the ability of a particular mixture to reproduce a particular property, there is usually a desire to employ surrogate mixtures that are physicochemically authentic. This means that, provided that the primary purpose is satisfied, researchers are inclined to choose mixtures that have physical and chemical properties appropriate to the finished fuel.

Surrogate mixture models were developed to represent the thermophysical properties of two samples of aviation turbine fuel Jet A [161]. One sample was a composite of numerous batches from multiple manufacturers and was considered to be a representative fuel. A second sample, while still meeting the fuel specifications, contained a lower than normal aromatic content and was selected to demonstrate some of the compositional variability seen among different batches of Jet A fuel. A surrogate for each fuel was developed with a procedure that incorporated experimental data for the density, sound speed, viscosity, thermal conductivity, cetane number, and the volatility (as indicated by advanced distillation curves) for samples of the two fuels. The surrogates were simple mixtures containing eight or fewer components, yet they can represent the thermophysical properties of actual real fluids that are very complex mixtures of hundreds of components.

The advanced distillation curve method was used as a means to evaluate the physicochemical authenticity of surrogate mixtures. While the strategy outlined here

can be used for any family of surrogates, it was applied to surrogate mixtures for Jet A/JP-8. Mixtures were divided into two groups: (1) simple surrogate mixtures with up to three components, and (2) complex surrogate mixtures with more than three components [162].

# Kerosenes

## Introduction

The *Encyclopedia of Liquid Fuels* contains eight chapters dealing with hydrocarbon fuels. The topic of hydrocarbon fuels had to be subdivided into several smaller chapters that were easier to arrange in alphabetical order in five subvolumes of equal size. The titles of the eight hydrocarbon chapters are: “Alkanes,” “Alkenes and Alkynes,” “Aromatic Hydrocarbons,” “Cycloaliphatic Hydrocarbons,” “Hydrocarbons,” “Jet Fuels,” “Kerosenes,” and “Ramjet Fuels.” The current chapter, “Kerosenes,” is an introduction to the chemistry and applications of hydrocarbons with high boiling points.

## 1 Kerosenes

This chapter on kerosenes is closely related to other chapters in the *Encyclopedia of Liquid Fuels*, such as the chapters on hydrocarbons, alkanes, cycloaliphatic hydrocarbons, aromatic hydrocarbons, jet fuels, and ramjet fuels. Various grades of kerosenes have been used for propulsion since petroleum fuels were first discovered. Most of the kerosenes in the early days were of the diesel fuel grade. Eventually, different grades of kerosene for jet fuel became available and many of those were used as rocket propellant fuels as well because they were readily available [1–4]. Efforts are continuing to improve the performance of kerosene fuels [5]. See also Sargent [6] and McCoy [7]. It is sometimes useful to look back at the history of kerosenes as military jet fuels to better understand their limitations and to appreciate the work that has been done to improve them [8, 9]. To some extent the improved kerosenes for rocket engines have benefited from this development, which was predominantly aimed at improving fuels for airbreathing jet engines.

There are many more publications on the properties of kerosenes as aircraft fuels than there are publications on kerosenes as rocket fuels. Literature summaries of the physical properties of kerosenes, regardless of what stimulated their creation in the first place, are useful for both applications and a short list of these publications (some now only of historical value) is offered here [10–15].

Some of these hydrocarbon fuels were also evaluated as fuels for pulse detonation engines or rotating detonation engines, which will be described in future volumes of the *Encyclopedia of Rocket Propellants*, such as *Encyclopedia of Non-Hypergolic Bipropellant Combinations*.

Until the 2010s, it was common practice to design booster stage rocket engines so that they would be used only once and then discarded. One of the limiting issues that prevented the reusability of those liquid oxygen (LOX)/kerosene engines was coke

deposition in the cooling channels of regeneratively cooled engines. Both design changes and strict use of thermally more stable kerosenes have enabled reusable launch vehicles. The three special grades of RP-1 listed in Table 1 were evaluated for use in reusable engines.

**Table 1:** Sulfur content of RP-1 grades

| Total Sulfur (TS) content, ppm | RP-1 Grade     |
|--------------------------------|----------------|
| < 500                          | Standard       |
| < 30                           | TS-30          |
| < 5                            | TS-5           |
| < 0.1                          | UL (Ultra-Low) |

The selection criteria for kerosenes as rocket fuels evolved gradually while a better understanding of the effects of molecular composition on the quality of heat transfer in regeneratively cooled engines developed and methods for the avoidance of coke deposition were found.

In the early days of rocketry, for logistic and economic reasons, it appeared desirable to design large rocket engines to operate on cheap, readily available hydrocarbon fuels without considerations of their source and reproducibility. When this shift in fuel was attempted, serious difficulties were encountered. This led to a considerable effort to improve the propellant performance by various means, including additives to the fuel. The shift to hydrocarbon fuels was accomplished with relatively little difficulty in engines employing liquid oxygen as the oxidizer. The absence of major difficulties at this stage probably inspired a false feeling of confidence that large rocket engines could satisfactorily employ any current specification air-breathing jet engine fuel. Until then, no specification existed for a hydrocarbon fuel specifically for rocket engines. Specification MIL-F-25576A for RP-1 fuel, originally issued 8 May 1956, represented the first concrete result of a joint effort by the Air Research and Development Command and Rocketdyne to arrive at a hydrocarbon fuel composition that would best suit the needs of large rocket engines as opposed to airbreathing jet engines.

The significance of composition and physical properties of blended hydrocarbon fuels on the performance of large rocket engines was investigated early on [16]. Results of a research program conducted at Rocketdyne to study the effects of the systematic variation of the fuel molecular type and molecular weight in bipropellant turbine gas generators and model rocket thrust chambers showed that a high aromatic content is deleterious to the performance of these combustion devices. Bipropellant turbine gas generators operate under very fuel-rich conditions to limit the exhaust gas temperature to the range that the pump turbine blades can tolerate. Soot formation is inevitable under these fuel-rich conditions. A highly naphthenic fuel within

the kerosene boiling range represents the best compromise among satisfactory thrust chamber and gas generator performance and good physical properties. Application of these criteria led to the development of RP-1 rocket fuel and Specification MIL-F-25576A, which was still new in the mid-1950s. In addition to kerosene fuel blends, pure heptane, *iso*-octane, *iso*-pentane, toluene, and methylcyclohexane were tested as model fuel compounds.

From a historical viewpoint it is interesting to learn that the word “kerosene” was once a trademark, registered as a <sup>TM</sup> trademark in 1854, and for several years, only the North American Gas Light Company and the Downer Company were allowed to call their lamp oil “Kerosene<sup>TM</sup>” in the United States [17].

## 2 Physical Properties of Kerosenes

Because the chemical composition of petroleum fractions differs substantially depending on the source of the crude oil, the chemical composition of hydrocarbon fuels is not used as a quality criterion. For each intended application a different set of physical and chemical property specifications has been created that serves for the procurement and the quality control of stored and transported fuels. A summary of physical properties of kerosenes used for air-breathing engines is given in Table 2. Some of these are the numbers contained in fuel specifications and may not necessarily represent average measured properties of currently used fuel blends. Other numbers are the results of field surveys, with numerous samples taken from the flight line.

### 2.1 Density and Coefficient of Thermal Expansion of Kerosenes

Because the chemical composition of kerosenes differs from sample to sample, it is difficult to assemble a list of physical properties for engineering calculations. It has been attempted to establish a correlation of physical properties (examples are coefficient of thermal expansion, thermal conductivity and heat capacity shown below) by normalizing them in relation to the density of the sample, which is easy to determine. As an example of a physical property correlated to the density, Table 3 gives the coefficient of thermal expansion  $\beta = 1/V \, dV/dt$  for four kerosenes of different densities.

Table 2: Summary of physical properties of kerosenes.

| Property                                             | JP-4                               | JP-5                            | JP-7                              | JP-9                              | JP-10                           | RJ-4                            | RJ-5                            | RJ-6                            |

Data source: [18]

The North American petroleum industry often uses the American Petroleum Institute (API) scale to describe the density of petroleum distillates. The physical density can be converted to degree API by using the following formula:

$$^{\circ}\text{API} = (141.5/\rho \text{ at } 15.6^{\circ}\text{C}) - 131.5$$

where  $^{\circ}\text{API}$  is the degrees on the API scale and  $\rho$  is the density at  $288.7\text{ K} = 15.6^{\circ}\text{C}$  in  $\text{g/cm}^3$ .

## 2.2 Equation of State of Kerosenes

It is difficult to obtain accurate equations of state for kerosenes such as RP-1 or JP-8 because the composition of the samples may vary from case to case. The equations of state of surrogate fuel mixtures with known compositions can be predicted from empirical data bases and theoretical correlations [19]. The NIST ThermoData Engine is a large electronic database containing experimental data with detailed descriptions of relevant metadata that incorporates expert-system software to automatically generate dynamically on-demand equations of state [20]. The resulting equation of state (EOS) formulations for pure chemical compounds are used to develop a surrogate mixture model to represent the volatility behavior, as expressed by the distillation curve, of paraffinic fuels.

## 2.3 Compressibility of Kerosenes

The velocity of sound and the adiabatic compressibility for JP-3 and JP-4 are summarized in Table 4.

**Table 4:** Velocity of sound and adiabatic compressibility of JP-3 and JP-4.

|               | Density at 25 °C,<br>g/cm <sup>3</sup> | Velocity of sound at 25 °C,<br>m/s | Adiabatic compressibility,<br>m <sup>2</sup> /kg |
|---------------|----------------------------------------|------------------------------------|--------------------------------------------------|

| JP-3 Sample b | 0.7682                                 | 1233.8 ± 2                         | —                                                |
| JP-4 Sample a | 0.7757                                 | 1242.2 ± 1                         | 8.40 × 10 <sup>-9</sup>                          |
| JP-4 Sample b | 0.7762                                 | 1242.3 ± 1                         | —                                                |

Data sources: [21–23]

The isothermal compressibility coefficient of RP-1 is  $4 \times 10^{-6} \text{ psi}^{-1}$ . The temperature change of RP-1, entering the system at 288 K, as the result of adiabatic compression while passing through a pump were calculated to be 0.3 °C for every 0.68 MPa = 6.8 atm = 100 psia pressure increase [24]. This is only a very small change, but nevertheless it can have an effect on some of the temperature-dependent phenomena in a liquid propellant feed system (oscillations, cavitation).

When measuring the compressibility of RP-1, it was difficult to account for the chemical composition, which varied from sample to sample. A better correlation was possible by introducing a new temperature-dependent auxiliary parameter  $J$ , which is the volume modulus [25]:

$$J = \frac{1}{\rho \sqrt{\log 1000v}}$$

where  $\rho$  is the density in g/cm<sup>3</sup> at 288.7 K = 15.6 °C = 60 °F and  $v$  is the kinematic viscosity in cSt at 310.9 K = 37.8 °C = 100 °F. For the density range allowed for RP-1, the kinematic viscosity at 310.9 K = 37.8 °C = 100 °F is between 3.185 and 1.25 cSt. See Table 5.

**Table 5:** Isothermal compressibility of RP-1.

| Temperature, °C | 0                                                       | 30    | 75    | 150  | 225  | 300  |
|-----------------|---------------------------------------------------------|-------|-------|------|------|------|
| $J^a$           | Isothermal compressibility in $1/\text{at} \times 10^4$ |       |       |      |      |      |
| 0.64            | 0.556                                                   | 0.631 | 0.774 | 1.15 | 1.73 | 2.74 |
| 0.66            | 0.562                                                   | 0.638 | 0.792 | 1.18 | 1.79 | 2.86 |
| 0.68            | 0.567                                                   | 0.648 | 0.806 | 1.21 | 1.85 | 2.97 |
| 0.70            | 0.571                                                   | 0.655 | 0.824 | 1.24 | 1.90 | 3.09 |
| 0.72            | 0.576                                                   | 0.667 | 0.840 | 1.28 | 1.96 | 3.20 |

<sup>a</sup>  $J$  is a temperature-dependent volume modulus auxiliary parameter defined above.

## 2.4 Thermal Conductivity of Liquid Kerosenes

The thermal conductivity of liquid kerosene can be calculated from the following empirical formula:

$$\lambda = \frac{0.278226 \times 10^{-3}}{\rho} (1 - 5.4 \times 10^{-4} t)$$

where  $\lambda$  is the thermal conductivity in  $\text{cal cm}^{-1} \text{s}^{-1} \text{°C}^{-1}$ ,  $\rho$  is the density in  $\text{g/cm}^3$ , and  $t$  is the temperature in  $\text{°C}$ . The thermal conductivity of four kerosenes with different densities is listed in Table 6.

**Table 6:** Thermal conductivity of four kerosenes with different densities.

| Temperature |     | Thermal conductivity, $\text{cal cm}^{-1} \text{s}^{-1} \text{°C}^{-1}$ <sup>a</sup> |                         |                         |                         |
|-------------|-----|--------------------------------------------------------------------------------------|-------------------------|-------------------------|-------------------------|
| K           | °C  | Density, $\text{g/cm}^3$                                                             |                         |                         |                         |
|             |     | 0.78                                                                                 | 0.80                    | 0.82                    | 0.84                    |
| 273         | 0   | $0.3567 \times 10^{-3}$                                                              | $0.3476 \times 10^{-3}$ | $0.3394 \times 10^{-3}$ | $0.3311 \times 10^{-3}$ |
| 366         | 93  | $0.3388 \times 10^{-3}$                                                              | $0.3303 \times 10^{-3}$ | $0.3223 \times 10^{-3}$ | $0.3146 \times 10^{-3}$ |
| 477         | 204 | $0.3174 \times 10^{-3}$                                                              | $0.3094 \times 10^{-3}$ | $0.3019 \times 10^{-3}$ | $0.2947 \times 10^{-3}$ |

<sup>a</sup> calculated from the equation above.

Data source: [18]

The thermal conductivity of D. Eng. R. D. 2495, a kerosene with a boiling range of 443 to 523 K (170 to 250  $\text{°C}$ ) once used in the UK, was measured between 288 and 598 K (15 and 325  $\text{°C}$ ) and 0.1–20.3 MPa (1–200 atm) [26].

## 2.5 Heat Transfer Properties of Kerosenes

Kerosenes are often used as a regenerative coolant in very large rocket engines, such as the F-1 used in the SATURN-V Apollo-era launcher and the Russian RD-180 used in ATLAS-V EELV. The heat transfer properties of kerosenes need to be known in order to accurately size the cooling channels and select the operating conditions in a regeneratively cooled rocket engine. The operating conditions must be selected such as to avoid the formation of coke in the cooling channels. Heat transfer to kerosenes becomes unpredictable in supercritical regimes [27].

The convective heat transfer and pressure drop characteristics of a kerosene hydrocarbon fuel were investigated in an electrically heated minichannel with an inside diameter of 2.0 mm, within the range of fuel temperature 298–873 K (25–600  $\text{°C}$ ) at near-critical pressures [28]. In the single-phase liquid flow, considerable free convec-

tion in laminar flow stabilizes the flow at Reynolds numbers up to 3600, the heat transfer coefficients can be predicted by Gnielinski correlation with deviations no more than 20%, but at  $Re > 4000$  heat transfer enters a different regime. The adiabatic friction factor agreed with the Moody diagram and Blasius correlation at laminar and turbulent flow. As fuel temperature approached the pseudo-critical point, a peak and trough in heat transfer coefficients were recorded. First, heat transfer was enhanced by boiling or pseudo-boiling at the relevant pressures. As fuel temperature increased, heat transfer deteriorated, accompanied by acoustic flow instability and a peculiarly diabatic pressure drop deduction due to the steep thermodynamic properties. The heat transfer and flow stability were regained as the bulk fuel temperature increased to above the pseudo-critical points. Upon increasing the pressure, the singularities of heat transfer and fluid flow gradually disappeared.

The heat transfer characteristics of hydrocarbon fuels were investigated in short horizontal tubes with an inside diameter of 1.0 mm [29]. The experiments were conducted in test tubes that were 46 and 116 mm in length at a supercritical pressure of 3.0 MPa. The experimental parameters included a liquid velocity of 0.21–1.20 m/s, an inlet fluid temperature of 298–673 K, and various heat fluxes. Different heat transfer regions were designated based on the heat transfer behavior. Heat transfer was improved by thermophysical property variation, thermoacoustic oscillation, and endothermic reactions of the hydrocarbons. Heat transfer deterioration was characterized by gas resistance and coke deposition in the boundary fluid layer. The maximum safe ratios between heat flux and mass flow rate at various velocities and inlet fluid temperatures were determined and could be used as design criteria.

The design of cooling channels in regenerative cooling systems for scramjets or rockets requires knowledge of heat transfer properties of kerosenes. Correlations for heat transfer in kerosene flowing upward and downward in vertical tubes were developed and four existing correlations were assessed against available experimental data [30]. To further improve the prediction accuracy of the heat transfer of supercritical kerosene, a new dimensionless parameter ( $Q_i$ ) relevant to the heat flux was proposed and introduced into the development of a new correlation. Verification showed that the new correlation is more accurate than existing correlations.

An experimental investigation was performed on the convection heat transfer of a supercritical hydrocarbon fuel in a long capillary tube [31]. The horizontal test tube had an inner diameter of 1 mm and a length-to-diameter ratio of 980, dimensions that are close to those of practical interest heat-transfer channels in the thermal management system for hypersonic vehicles. The heat-transfer regions of hydrocarbon fuel were classified into initial heat transfer, normal heat transfer, enhanced heat transfer, and deteriorated heat transfer. The heat transfer coefficients of hydrocarbon fuels are affected by large variations in thermo-physical properties and buoyancy effects.

Under certain conditions of initial fluid temperature, the difference between wall temperature and fluid temperature, and above certain temperatures near the criti-

cal temperature, destructive pressure oscillations may occur in most fluids, including kerosenes. Pressure oscillations increase the rate of heat transfer. There are additional publications studying this phenomenon in specific kerosenes, such as RP-1 or RP-3.

Pressure oscillations in supercritical Jet-A fuel flowing through four parallel, heated tubes connected to common manifolds have been observed [32]. Tests were performed with fuel inlet temperatures ranging from 366 to 589 K (200 to 600 °F). Each tube received 2.26 kg/h of fuel. Tubes were heated by blowing 728–739 K (850–870 °F) hot nitrogen over them. Oscillations occurred when fuel inlet temperature was at least 422 K (300 °F). Amplitudes increased as fuel inlet temperature was increased. Maximum amplitudes encountered had frequency content ranging from 0.5 to 3 Hz for all oscillating cases.

Nucleate boiling heat transfer may induce oscillations under near-boiling conditions in any fluid, including kerosenes. The thermo-acoustic instability and heat transfer coefficients of an endothermic hydrocarbon fuel were investigated in a horizontal mini tube at supercritical pressures [33].

Experiments examining thermo-acoustic instability of hydrocarbon fuel flowing in horizontal circular tubes under various conditions indicated that there is a transition from stability to thermo-acoustic instability [34]. Results obtained with the method of Multi-Scale Shannon Wavelet Entropy based on Wavelet Transform Correlation Filter and Multi-Scale Shannon Entropy demonstrated that the induction of thermo-acoustic instability from noise and weak signals can be detected and the differences among stable operation, the transition phase, and the fully developed instability can be identified. The method can alert designers that thermo-acoustic instability of hydrocarbon fuel flowing in scramjet cooling channels may occur. The mass flow rate and the inlet pressure determine the point of transition to thermo-acoustic instability. This investigation of thermo-acoustic instability dynamic characteristics at supercritical pressures based on the wavelet entropy method defined the safe scramjet fuel flow rate, which can ensure stable fuel flow in regenerative cooling channels.

## 2.6 Thermodynamic Properties of Liquid Kerosenes

### 2.6.1 Heat Capacity of Liquid Kerosenes

The specific heat of liquid kerosene within the range 273 to 700 K can be calculated from the following formula (accurate to  $\pm 2\%$ ) [18]:

$$c_p = \frac{1}{\sqrt{\rho_{15.6}}} \left[ 0.388 + 4.5 \times 10^{-4} \times (1.8t + 32) \right]$$

where  $c_p$  is the heat capacity in  $\text{cal g}^{-1} \text{ } ^\circ\text{C}^{-1}$ ,  $t$  is the temperature in  $^\circ\text{C}$ , and  $\rho$  is the density in  $\text{g/cm}^3$ . This equation gives the values summarized in Table 7. The specific heat

**Table 7:** Heat capacity of four liquid kerosenes with different densities.

| Density<br>g/cm <sup>3</sup> | Temperature |      | Liquid heat capacity                 |                                   |

Data source: [18]

of kerosene vapor can be extrapolated from the following equation (not very accurate, only good for first-order estimates):

$$c_p(\text{vapor}) = c_p(\text{liquid}) - 0.09/\rho.$$

The isobaric specific heat capacity of a kerosene-type hydrocarbon fuel at temperatures from 330 to 900 K and operating pressures from 1.96 to 4.93 MPa was measured using a flow calorimeter, which was based on the energy conservation theory [35]. The isobaric specific heat capacity data had an expanded relative uncertainty of 2.54%. The reliability and accuracy of the flow calorimeter measurement was verified using water, *n*-hexane, and binary mixtures of *n*-heptane + *n*-octane, and methanol + acetone respectively. In addition to kerosene, the isobaric specific heat capacities of a type of endothermic hydrocarbon fuel were measured and  $C_p$ - $T$  diagrams were plotted at sub- and supercritical pressures.

### 2.6.2 Enthalpy of Formation of Liquid Kerosenes

Because kerosenes are mixtures of hydrocarbons, thermodynamic properties that are usually reported on a per mole basis are difficult to compare. It would be more meaningful to list the enthalpy of formation on a mass basis (typically per 100 g). Different investigators have used different gross formulas and different formula weights (masses) for kerosenes. For instance, JP-4 has been described as CH<sub>2</sub>, C<sub>9</sub>H<sub>17</sub>, or C<sub>9.5</sub>H<sub>18.9</sub> and for each of these gross formulas the enthalpy of formation would be different if it was reported in the kJ/mol format. Enthalpy of formation data for kerosenes are compared in Tables 8 and 9.

### 2.6.3 Enthalpy of Evaporation of Liquid Kerosenes

For a crude approximation, the enthalpy of evaporation of kerosene at sea-level pressure can be expressed as a function of the liquid density and the temperature [18]:

$$\Delta H_{\text{evap.}} = \frac{0.5556}{\rho} [110.9 - 0.09(1.8t + 32)]$$

where  $\Delta H_{\text{evap}}$  is the enthalpy of evaporation in cal/g,  $t$  is the temperature in °C, and  $\rho$  is the density in g/cm<sup>3</sup>.

Correlation-gas chromatography was used to predict the evaporation enthalpy of complex fuels such as RP-1, JP-7, and JP-8 [38]. Evaporation enthalpies of 308, 341, and 441 kJ/kg were predicted assuming average compositions of C<sub>12</sub>H<sub>23.4</sub>, C<sub>12</sub>H<sub>25</sub>, and C<sub>11</sub>H<sub>21</sub> respectively. The hydrogen-to-carbon (H/C) ratio in these fuels has been measured by <sup>1</sup>H nuclear magnetic resonance (NMR), and an average molecular weight has been determined using gas chromatography (GC). Some variance in composition with the literature values has been observed. The predicted vaporization enthalpies were

compared with those in the literature. The effect of GC detector bias in evaluating the molar fraction of each hydrocarbon present, as a function of size, was tested and determined to have a relatively small effect on the vaporization enthalpy. Additional heat of sublimation data of hydrocarbons are available at Chickos and Acree [39].

## 2.7 Critical Point Properties of Kerosenes

The critical point properties of kerosenes are listed in Table 10.

**Table 10:** Critical point properties of kerosenes.

| Compound | $T_{\text{crit}}$<br>K | $p_{\text{crit}}$<br>MPa | References |
|----------|------------------------|--------------------------|------------|
| RP-1     | 676–689                | 2.140–2.170              | —          |
| JP-4     | Variable               | Variable                 | —          |
| JP-5     | 675                    | 2.27                     | [40]       |
| JP-8     | 666–684                | 2.344                    | [41]       |

## 2.8 Chemical Properties of Kerosenes

Hydrocarbons can be gases, liquids, or solids. At room temperature, alkanes with 5–16 carbon atoms in linear chains are liquids. The general gross formula for alkanes is  $C_nH_{2n+2}$ , the general gross formula for alkenes is  $C_nH_{2n}$ , and the general gross formula for alkynes is  $C_nH_{2n-2}$ .

The constituents of kerosene fuels can be generally classified in the following categories:

1. Hydrocarbon (HC) types
  - a. Paraffins ( $C_nH_{n+2}$ ) are mostly desirable as the main constituents of kerosenes such as JP-4 or RP-1. Paraffin alkanes are the natural constituent of many crude oils (aka “feedstocks”). Alkanes have the highest H/C ratio, which is a measure of the energy content of the fuel and is also regarded as a good indicator of stability. The paraffin fraction in crude oil can be increased by hydrotreating, thereby saturating the aromatic and olefin types. Depending on pressure and flow rate, paraffins are resistant to cracking at temperatures  $< 811$  K. The biggest problem with normal paraffins is their relatively high freezing point. This potential problem is eliminated by mixing normal paraffins with branched paraffins, which maintain the desired properties of the paraffin, but with better low temperature properties.
  - b. Naphthenes or cycloparaffins ( $C_nH_{2n}$ ) are desirable constituents for rocket propellant fuels. Naphthenes are natural constituents of some crude oils. The

naphthenes fraction depends on the origin of the feedstock. Naphthenes are more thermally stable than paraffins and may passivate reactive hydrocarbon constituents formed in heated fuel. Highly branched cycloparaffins have extremely low freezing points due to the asymmetry of the molecule. The ideal kerosene fuel would be a mixture of the branched and cyclic paraffins. Increasing the naphthenic content improves the thermal stability of the fuel. This can be accomplished by either using naphthenic crude oil feedstocks available on the West Coast, or by catalyzed isomerization during the refinement process (which might elevate fuel cost).

- c. Aromatics are undesirable for rocket propellant fuels. Aromatics are natural constituents of many crude oils. A low H-number or H/C ratio is a characteristic of a high fraction of aromatics in the fuel. Aromatics have poor ignition and combustion properties, increase flame radiation (which can produce plume heating issues in the rocket exhaust) and can cause deposition of coke at temperatures greater than  $\sim 533\text{K}$ . Aromatics are not desirable components for any fuel used in gas turbines or rocket engines. Aromatics content can be minimized by hydrotreating to form the corresponding naphthenes.
  - d. Olefins are highly undesirable in any fuel mixture, jet engine fuel, or rocket fuel. Olefins are highly unstable and are not a large natural constituent of crude oil. The olefin fraction in crude oil can be minimized/eliminated by hydrotreating. Olefins will degrade in ambient temperature storage to produce insoluble gums in fuels.
2. Non-hydrocarbon (HC) types
- a. Sulfur is a highly undesirable constituent of hydrocarbon fuels. Sulfur is a natural constituent of most (“sour”) crude oils in the form of thiols/mercaptans, sulfides, and thiophenes. Thiols and sulfides are primary initiators in the degradation process by producing reactive hydrocarbon constituents. This is specifically prevalent when exposed to copper-based alloys (i.e., coolant liners), where the sulfur reacts to form  $\text{Cu}_2\text{S}$  deposits and corrosion on the metal. The sulfur content becomes more troublesome at fuel temperatures  $> 644\text{K}$ . Sulfur-containing components can be minimized by hydrotreating to remove thiols and sulfides.
  - b. Dissolved oxygen in kerosene is undesirable but is usually introduced into kerosene by exposure to ambient air. Oxygen plays a role in the thermal stability of the fuel, but is a transient phenomenon that is a function of the storage history of the fuel. Oxygen reacts with unstable constituents and contributes to decomposition by producing reactive contaminants during storage. Sparging with nitrogen gas can remove dissolved oxygen from the fuel. Sparging is a physical process that involves bubbling nitrogen through the fuel for a period of time. The nitrogen gas will replace the dissolved oxygen in the fuel.

- c. Gums in kerosene are highly undesirable. Gums are higher molecular weight residues formed during the refining process or introduced into fuel from contaminated storage tanks and transfer lines. Originally, gums were thought to be mainly formed from olefin polymerization. Gums can contribute to the formation of deposits on metal surfaces and fouling. Gums are susceptible to thermal decomposition.

### 2.8.1 Thermal Decomposition of Kerosenes

The thermal decomposition of kerosenes is a standard process in petroleum refining in order to obtain lower boiling fuels. The product distribution and the kinetics of cracking of kerosene were investigated in a pilot plant under varying conditions of residence time, temperature, total pressure, and dilution close to those used in industrial operations [42]. The influences of feed composition, total pressure, and inlet partial pressure on the product distribution were determined. Kinetics of the cracking of individual components in the kerosene mixture were also calculated.

New challenges to increase aircraft speeds and engine efficiencies are increasing vehicle aerodynamic friction heat loads. Exotic alloys have been used for the shell of supersonic airplanes such as the X-15 and the SR-71/YF-12 (Black Bird). The leading edges may have to be cooled to prevent them from losing structural integrity and melting. Especially at higher Mach numbers, fuel is an attractive heat sink. For many vehicle applications, utilization of this heat sink would increase fuel temperatures beyond the limits of thermal stability, typically 643–673 K (370–400 °C). As temperatures increase beyond about 753 K (480 °C), this heat addition can lead to thermal/catalytic cracking of the fuel, leading to an “endothermic” fuel. The principal barrier to the use of high-temperature fuels is the deposition of carbonaceous material on heat exchanger passages, filters, fuel injectors, and other fuel system components [43].

There is concern that rocket engine regenerative cooling system performance and reliability may be negatively impacted by compositional variation even for kerosene fuels meeting existing specification limits. One must identify all potential compositional variations and quantify their influence on cooling characteristics. Rocket-grade kerosene is not typically quality tested for thermal stability or material compatibility prior to delivery and use in current launch vehicles. Specifically, RP-1 is not tested and RP-2 is tested only using American Society for Testing and Materials (ASTM) D3241 (Standard Test Method for Thermal Oxidation Stability of Aviation Turbine Fuels [Jet Fuel Thermal Oxidation Tester, JFTOT, Procedure]), but results are only reported, not constrained by specification limits. The JFTOT procedure, as specified in MIL DTL-25576E, is unable to adequately discriminate between thermally stable rocket fuels that have been shown in higher fidelity testing to perform differently or even fail.

The pyrolysis of a jet fuel consisting mostly of *n*-alkanes was experimentally and numerically studied in a tube reactor heated by fluidized sand under supercritical conditions [44]. The pyrolysis of aviation kerosene at different temperatures (798–873 K =

525–600 °C in 25° increments) and flow rates (1–6 mL/min) were experimentally studied under supercritical pressures (3.5 MPa) and the conversion rates and product distributions under different conditions were measured. The equivalent residence time was calculated by computational fluid dynamics (CFD) simulations with the concept of equivalent volume. On this basis, a molecular kinetic reaction model including 16 substances and 11 reactions was developed. The experimental and predicted results using the developed kinetics model agreed well, with deviations of less than 10% at conversions of up to 70%. The pyrolysis model was also used in modeling fuel flowing and pyrolysis in an electrically heated tube showing conversion prediction errors of less than 15% and fuel and wall temperature prediction deviations less than 20 K, which was a significant improvement over a previous model.

### 2.8.2 Coke Deposition of Hydrocarbon Fuels

Coking, with regard to hydrocarbon fuels, has been defined as the deposit formation of mostly solid-state carbon in the cooling channels of a hydrocarbon fuel-cooled combustion chamber. Coke formation appears to be influenced by the following parameters:

- a. Hydrocarbon fuel composition. For example, because of its inherent stability, the composition of methane is less prone to coking than higher-molecular-weight hydrocarbons. Liquid fuel high-temperature stability can be predicted from an *a priori* knowledge of the primary hydrocarbon types present in the fuel.
- b. Operating fuel pressure
- c. Hot wall temperature
- d. Catalytic activity of fuel-wetted surface material (i.e., copper alloy coolant liners promote faster deposit formation than stainless steel)
- e. Fuel flow velocity (i.e., fast-flowing fuel reduces the residence time for which the fuel is exposed to the hot wall)

Coking is undesirable for several reasons. Even present as a thin surface coating, it can restrict the flow of heat to the bulk coolant, thus causing coolant channel temperature increases, which ultimately cause failure and burnout. In larger quantities, coke deposition could progressively restrict the flow of fuel through the coolant passages and increase the pressure drop.

#### 2.8.2.1 Methods for Determination of Coke Deposition

Thermal stability of kerosenes is critical to prevent coke deposition in the channels of a regenerative cooling system. This property is very difficult to determine and it is difficult to obtain reproducible results. Methods for the quantitative determination of a tendency of a hydrocarbon fuel blend toward coke deposition have evolved during the past six decades. Some of these older methods are now only of historical interest.

Comparisons were made between the visual results obtained with a coker and the results obtained with a small, highly-instrumented Minex heat exchanger [45]. The comparisons showed that a reasonable correlation between the results obtained with the heat exchanger and with the coker may be achieved if three or more coker tests are analyzed on the basis of tube wall temperature versus deposit rating. By measuring the thickness of the film deposited and by knowing the effect of this thickness on heat transfer, a thermal conductivity can be calculated.

Six different jet fuels were tested for their resistance to thermal coke deposition by two versions of the CRC modified coker and the Minex heat exchanger [46]. The test results were compared by plotting the coker deposit code rating versus coker–preheater-tube wall temperature. The temperature of the tube wall, where large quantities of deposits form, was compared with the temperature of the Minex fuel outflow, where tube fouling due to deposits occurs. Fouling was indicated by a change in the measured heat transfer coefficient. The relative ranking of the six fuels was the same on the Minex as on the helium-driven modified coker. The pump-driven modified coker, however, gave a relative ranking that correlated with neither the Minex nor the gas-driven coker. It was concluded that the pump-driven modified coker was not a satisfactory test tool for fuels with a resistance to thermal degradation above 533 K (500 °F). It was apparent that the pump on the coker was affecting the test results when fuels of high thermal stability were tested. The most obvious reason for this effect was that the fuels with thermal stability above 533 K (500 °F) were treated to remove trace materials, and that these trace materials provide a degree of boundary lubrication in the pump. Without this degree of boundary lubrication, the coker pump may wear and release wear products (metal particles) that affect the test results.

The test recommended to measure the thermal stability of kerosenes is the JFTOT. Although the majority of the test methods described here were developed for jet engine fuels, they can be equally well used for evaluating the thermal stability of kerosenes for rocket engines.

The thermal stability test is conducted in accordance with a modified version of (IAW) ASTM D 3241 (JFTOT). The JFTOT test conditions are:

- a. Heater tube temperature at maximum point:  $628\text{ K} = 355^\circ\text{C} = 671^\circ\text{F}$
- b. Fuel system pressure:  $3.45\text{ MPa} = 34\text{ atm} = 500\text{ psi}$
- c. Fuel flow rate:  $3.0\text{ mL/min}$
- d. Test duration: 300 min
- e. Quantity of test fuel: 1 L

The heater tube is inspected after the test and the amount of coke formed is rated visually on a scale. The post-test heater tube is rated for deposits using the Alcor Mark 8A Tube Deposit Rater (TDR). The Alcor Mark 8A TDR is described in ASTM D 3241.

Comparisons were made between the JFTOT and the ASTM-CRC Coker Test (D 1660), which could be replaced with a new laboratory test device [47]. The JFTOT represents another method for rating the deposit-forming tendencies of

hydrocarbon fuels. It utilizes the same principle as the ASTM CRC Coker with certain improvements and was expected to be comparable with the Coker in ranking fuels. The JFTOT has the following operating advantages over the Coker: smaller sample size, shorter test time, easier operation, better tube temperature control, higher temperature capability, and higher fuel system pressure to minimize two-phase flow. The precision of determining maximum deposits is about the same with both tests. Precision of measuring test filter pressure drop in the JFTOT is significantly better than the Coker. The precision of measuring “breakpoint” temperature in the JFTOT is significantly better than the Coker. The JFTOT operated at a heater tube control temperature of 516 K (243 °C) should provide the same pass–fail criteria as the Coker operated at a fuel outflow control temperature of 422 K (149 °C). A light-reflectance method for rating tube deposits was found to be more precise than the visual method used with the Coker. Although there is a general relationship between the two rating methods, they are not exactly interchangeable.

The Visual Rating method and the ALCOR Mark 8A Tube Deposit Rater, used to rate deposits that form on the JFTOT heater tubes, were compared with each other and with measurements of the deposit thickness [48]. An Auger Electron Spectrometer, used in conjunction with an ion gun (AES/Ion Gun), was used to measure the deposit thickness and composition. Both the Visual Rating method and the Mark 8A Tube Deposit Rater were found to correlate with deposit thickness measurements to a limited degree. The AES/Ion Gun method proved to be a useful laboratory tool for measuring the thickness of coke deposits and the elemental composition of deposits (except for hydrogen and helium). Deposits that have a spectrum of colors (i.e., peacock or rainbow-type colors) were found to be considerably thicker than Code 3 deposits. Thin-film light interference (similar to colors of oil sheen on water) was found to be the cause of the peacock colors associated with these deposits.

Earlier research performed by Shell Research sought to compare the performance of fuels in the JFTOT with that in a simulated engine oil cooler. However, the agreement between the rigs was poor and initial attempts to improve the correlation by modifying various JFTOT operating parameters were ineffective. Later, those same operating parameters were readdressed in more detail, in order to determine the physical and chemical factors that control fuel response in the JFTOT [49]. Flowrate experiments and activation energy measurements indicated not only that the JFTOT’s response to a fuel depends on the relative roles of chemical reaction and physical transport, but more significantly, the contribution of the two effects is fuel dependent. Studies of test section metallurgy revealed that although differences between aluminum and stainless steel were clearly discernible under certain conditions, such differences became irrelevant as fuel degradation proceeds and the metal surface becomes lacquered. The findings provided an explanation as to why no improvement could be made in the correlations exhibited by earlier experiments. Development of a different small-scale thermal stability test was suggested.

One measure of the thermal stability of aviation fuels is the quantity of deposits formed on heated metal surfaces. In accelerated stability tests conducted in accordance with the JFTOT procedure (ASTM D3241), the rating methods involve either visual comparisons or measurement of reflected light by the TDR, both of which are sensitive to deposit color and surface texture. Deposits formed on stainless-steel JFTOT heater tubes have been examined by the TDR, a gravimetric carbon combustion method, and two new non-destructive techniques for determining deposit volumes based on measurements of dielectric strength and optical interference [50]. Measurements of total carbon content by combustion were used as a reference. It was found that the dielectric and interference methods correlated well with the combustion analyses and each other, whereas the total TDR often yielded misleading results.

It was demonstrated that a Fourier transform-infrared (FT-IR) fiber optic probe and a quartz crystal microbalance (QCM) probe could be used to measure deposit formation from thermal stressing of jet fuels in a high-temperature, high-pressure flow system [51]. These probes were designed, constructed, and tested in an existing Fuel Stability Test System that had an FT-IR Attenuated Total Reflectance (ATR) circle cell monitoring the stressed fuel after cooling to ambient temperature. It was demonstrated that both the FT-IR fiber optic probe and the QCM probe could successfully differentiate between a 'stable' and an 'unstable' fuel. The results from the QCM probe tests indicated that the drop in frequency for this particular probe resulted from viscosity dampening and not the mass of the film. The changes in the bulk fuel composition from thermal stressing were measured with the ATR circle cell, and were found to be significantly different from the changes in the deposit layer composition measured by the fiber-optic probe.

A series of heat transfer tests with methane, propane, No. 21 high-density kerosene, aerokerosene, and rocket kerosene was conducted at pressures of 0.5–30 MPa, flow velocities of 2–106 m/s, and heat fluxes up to 66 MW/m<sup>2</sup> in stainless-steel and copper tubes, and the deposit formation rates for kerosene in tubes were measured [52]. Forced convective heat-transfer correlations were obtained for liquid methane, propane, and kerosene, up to extreme heat fluxes at which test tubes burnt out. The test results indicated that heat-transfer coefficients of methane and propane decreased at high wall temperatures, and that the coefficients of kerosene increased under similar conditions because of boiling. No coking was detected in methane tests. Coking temperature and coking rates were determined for kerosene in stainless-steel tubes.

A series of heat-transfer tests was conducted with JP-7, JP-8, JP-8+100, JP-10, and RP-1 in resistively heated tube sections to simulate conditions encountered in regeneratively cooled rocket engines [53]. Six tests were conducted for each fuel using a half-factorial test matrix with fuel average velocities set at 7.6 and 22.8 m/s (25 and 75 ft/s), wall temperatures of 672 and 811 K (750 and 1000 °F), and OFE 101 copper and stainless steel 304 as tube materials. Test section average pressure and fuel bulk outlet tempera-

ture were held constant at 6.8 MPa (1000 psi) and 533 K (500 °F), respectively whereas target run times for all tests were 20 min. Carbon deposition rates for all tests were comparable ( $\sim 100 \mu\text{g cm}^{-2} \text{h}^{-1}$ ) with the exception of the JP-8/JP-8+100 copper tests, which yielded deposition rates an order of magnitude greater ( $\sim 1000 \mu\text{g cm}^{-2} \text{h}^{-1}$ ). The heat-transfer data collected from all tests could be well correlated by a standard pipe flow equation, which yielded an  $R^2$  value of 0.96.

A laboratory-scale flow reactor was used to subject small amounts (approximately 1 ml) of deoxygenated hydrocarbon fuels to controlled conditions of temperature and residence-time-at-temperature at constant pressure (3.44 MPa = 34 atm) in the liquid or supercritical phase [54]. The reactor was made of CRES-316 HPLC tubing. The thermal stability of the fuels, as well as the thermal fragmentation products of each fuel was measured using an in-line analytical system, as well as off-line GC analysis of products. Some of the candidate materials tested (quadricyclane and bicyclopropylidene) showed only marginal thermal stability with major decomposition occurring below 673 K (400 °C) with only  $\sim 3$ -s residence time. Other candidate materials (JP-10, RP-1, RG-1, RJ-6, and RJ-7) showed excellent thermal stability and little decomposition even at 873 K (600 °C). Results showed the pyrolytic stability of candidate materials relative to each other, and provided insights into the mechanisms of thermal decomposition for specific fuel candidates.

An experimental research program to investigate the thermal performance of several candidate hydrocarbon rocket fuels used a series of test rigs of increasing complexity and fidelity to one after another screen identified fuels without the cost and complexity of a full engine system level test [55, 56]. Results of small-scale thermal decomposition experiments utilizing a System for Thermal Decomposition Studies test rig provided an initial evaluation of the thermal stability performance of fuels from very small fuel samples. Measurements of heat transfer coefficient and the effect of wall temperature, flow velocity, and wetted material on deposit formation in heated test channels were obtained from larger rigs, such as the NASA/GRC Heated Tube Facility and the Air Force Rocket Propulsion Laboratory (AFRPL)/PRS High Heat Flux Facility. Two major types of devices were used to obtain high-heat-flux-relevant conditions: electrically heated tubes and heated copper blocks. Electrically heated tubes generate heat by passing electrical current through a metal tube instead of wrapping it with a heater coil and are predominantly used to obtain high-heat-flux heat-transfer data [57].

Conduction heated rigs, such as Aerojet's Carbothermal test rig, developed under the Hydrocarbon-Materials Fuel/Chamber-Liner Compatibility Program in the late 1980s (NAS3-25070), offer the advantage of significantly lower electrical power requirements to generate simulation of high-heat-flux test conditions in cooling channels. AFRPL/PRS has undertaken design and construction of a conduction heated, High Heat Flux Facility, based on the Carbothermal test rig and incorporating extension of maximum-heat-flux test capability to  $16342 \text{ W/cm}^2$  (100 British thermal units [BTU] in  $^{-2} \text{ s}^{-1}$ ).

Until 2004, none of the existing thermal stability test rigs had the ability to accurately simulate the high heat flux conditions that will exist in the cooling channels of new high-pressure hydrocarbon engines. The Air Force Research Laboratory (AFRL) at Edwards AFB designed a High Heat Flux Facility (HHFF) using experience gained from past thermal stability test rig experiments [58]. In order to design a facility capable of simulating the higher heat fluxes expected in the channels, CFD++, a Metacomp Technologies Inc. computational fluid dynamics software suite, was employed to optimize the design prior to manufacture. Conjugate heat-transfer calculations were performed in a single computational domain containing the copper heater block and the fluid channel of the new test rig design. The parameters of interest during each experiment were the heat-transfer coefficient, the degree of coking and corrosion in the channel, and the pressure drop as a function of heat flux, wall temperature, Reynolds number, channel material, fuel composition, and pressure.

The JFTOT is a thermal stability test that measures the tendency for fuel to form deposits and delivers a pass/fail grade for each fuel tested. However, the extent of oxidation and the corresponding deposition occurring in the JFTOT is not fully understood. A JFTOT Model Mark II was modified to include a bulk outlet temperature measurement and a downstream oxygen sensor to measure bulk oxygen consumption [59]. Results showed a direct relationship between the bulk outlet temperature and JFTOT setpoint temperature with the bulk outlet less than the setpoint temperature. Several fuels were tested at varying setpoint temperatures with complete oxygen consumption by 593 K (320 °C) and a wide range of oxygen consumption from 10–85% at 533 K (260 °C). Simulations of coke deposition were of the right order of magnitude and matched the deposit profile of comparable experimental ellipsometry data.

### 2.8.2.2 Kinetics of Thermal Decomposition of Kerosenes

Fuel concentration time-histories and overall rates of gas-phase RP-1, RP-2, JP-7, *n*-dodecane, and 1,2,3,4-tetrahydroquinoline decomposition reactions were measured using laser absorption in an aerosol shock tube and a heated high-pressure shock tube [60–63]. Experiments were performed with 0.1 to 0.6% fuel/argon mixtures for temperatures between 1000 and 1400 K and pressures from 0.3 to 5.1 MPa (3 to 51 atm). Fuel concentration was measured by infrared laser absorption at 3.39  $\mu\text{m}$ . Fuel-removal data for *n*-dodecane were used to determine the unimolecular decomposition rate constant for the reaction *n*-dodecane  $\rightarrow$  products.

The thermal decomposition kinetics of JP-7, JP-TS, and JP-900 were studied at 648, 673, 698, and 723 K (375, 400, 425, and 450 °C) in stainless-steel bomblet reactors [64]. In all cases, the pressure before decomposition was adjusted to 34.5 MPa (5000 psi). Decomposition as a function of time at each temperature was quantified by analyzing the thermally stressed liquid phase using GC. These results were used to determine global first-order rate constants that approximate the overall decomposition rate of each fuel. For JP-7, these first-order rate constants ranged from  $1.79 \times 10^{-5} \text{ s}^{-1}$  at 648 K (375 °C) to  $3.02 \times 10^{-4} \text{ s}^{-1}$  at 723 K (450 °C). For JP-TS, the rate constants were between

$1.74 \times 10^{-5} \text{ s}^{-1}$  at 658 K (375 °C) to  $2.70 \times 10^{-4} \text{ s}^{-1}$  at 723 K (450 °C). For JP-900, the rate constants ranged from  $1.03 \times 10^{-5} \text{ s}^{-1}$  at 648 K (375 °C) to  $3.60 \times 10^{-4} \text{ s}^{-1}$  at 723 K (450 °C). At all temperatures studied, these three fuels have similar rate constants for thermal decomposition; with only one exception, the values of  $k'$  were identical within the combined uncertainty. The rate constants for the decomposition of RP-2, a fuel being considered as a replacement fuel for hypersonic vehicles, were similar within the temperature range studied. Considering the time needed for 1% of the sample to decompose ( $t_{0.01}$ ), we find that required instrument residence times range from 16 min at 648 K (375 °C) to 30 s at 723 K (450 °C). The rate constants as well as the Arrhenius parameters can be used to design and plan physical property measurements at additional temperatures.

### 2.8.2.3 Experimental Study of Coke Deposition in Regeneratively Cooled Rocket Engines

There are numerous test methods for the measurement of the coking (“fouling”) tendency of hydrocarbon fuels subjected to high temperatures in contact with metal surfaces. Some tests measuring the rates of coke deposition were combined with an evaluation of the compatibility with and potentially catalytic activity of the metals from which cooling channels in rockets are built. The test methods were already described in Section 2.8.2.1 above. The following is a summary of results obtained by various investigators with several fuels using different experimental methods. Sections on thermal stability and coke deposition of specific hydrocarbon fuels will follow under the headings of individual hydrocarbon fuels.

Oxidation and condensation products of a standard jet fuel at 463–473 K (190–200 °C) have been concentrated and fractionated to give materials of average molecular weight of  $>300$  by (1) precipitation from pentane and (2) gel permeation chromatography [65]. Heating fuel with stainless steel wool and oxygen at 473 K (200 °C) formed insoluble deposits that could be removed only by heating in air. A deposit from a simulated fuel manifold has been analyzed.

A high-pressure fuel coking test apparatus was used to evaluate thermal decomposition (coking) limits and carbon deposition rates in heated copper tubes for two hydrocarbon fuels, RP-1 and commercial-grade propane [66, 67]. Tests were conducted using JP-7 and chemically pure propane as being representative of more refined cuts of the baseline fuels. A parametric evaluation of fuel thermal stability was performed at pressures of 136 to 340 atm, bulk fuel velocities in the range 6–30 m/s, and tube wall temperatures within the range 422–811 K. The effect of the inside wall material on deposit formation was evaluated in selected tests using nickel-plated tubes. The results of the tests indicated that substantial deposit formation occurred with RP-1 fuel at wall temperatures between 600 and 800 K, with peak deposit formation occurring near 700 K. No improvements were obtained when deoxygenated JP-7 fuel was substituted for RP-1. The carbon deposition rates for the propane fuels were generally higher than those obtained for either of the kerosene fuels at any given wall tempera-

ture. Plating the inside wall of the tubes with nickel was found to significantly reduce carbon deposition rates for RP-1 fuel.

An experimental research program was undertaken to investigate the thermal stability and heat-transfer characteristics of several hydrocarbon fuels under conditions that simulate high-pressure, rocket engine cooling systems [68–70]. The rates of carbon deposition in heated copper and nickel-plated copper tubes were determined for RP-1, propane, and natural gas using a continuous flow test apparatus that permitted independent variation and evaluation of the effect on deposit formation of wall temperature, fuel pressure, and fuel velocity. The effects of fuel additives and contaminants, cryogenic fuel temperatures, and extended duration testing with intermittent operation were examined. Parametric tests to map the thermal stability characteristics of RP-1, commercial-grade propane, and natural gas were conducted at pressures of 6.9 to 13.8 MPa, bulk fuel velocities of 30 to 90 m/s, and tube wall temperatures within the range 230 to 810 K. Tests were run in which propane and natural gas fuels were chilled to 230 and 160 K respectively. Corrosion of the copper tube surface was detected for all fuels tested. Plating the inside of the copper tubes with nickel reduced deposit formation and eliminated tube corrosion in most cases. The lowest rates of carbon deposition were obtained for natural gas, and the highest rates were obtained for propane. For all fuels tested, the forced-convection heat-transfer film coefficients were satisfactorily correlated using a Nusselt–Reynolds–Prandtl number equation.

Coking and heat transfer characteristics of three hydrocarbon fuels in heated tubes were compared. RP-1, RP-1/DAH, and JP-7 hydrocarbon fuels were tested in electrically heated tubes to determine and compare their heat-transfer characteristics and thermal stability [71]. Tube materials of Ni 200 and SS 347 were used, and coolant-side wall temperatures of 644, 755, and 866 K (371, 482, and 593°C) were tested. Fuel flow conditions were set to match the conditions in the regenerative coolant channels of typical LOX/hydrocarbon expendable rocket engine systems. Results showed that JP-7 has a 4.5% higher specific heat capacity than RP-1 and very little coke deposition on the tube walls. The specific heat of the RP-1/DAH fuel was similar to that of the RP-1 fuel. The coke deposition of the RP-1/DAH fuel, however, was much heavier than that of the baseline RP-1 fuel. It was evident throughout the Ni 200 tubes in nodules that grew as high as 0.041 mm above the surface.

A materials compatibility and thermal stability investigation was conducted under environmental conditions similar to those encountered in regeneratively cooled rocket engines using five common liquid hydrocarbon fuels and two structural materials [72]. Scanning-electron microscopic analysis in conjunction with energy dispersive spectroscopy (EDS) was used to characterize the condition of the tube inner wall surface and any carbon deposition or corrosion that was formed during selected runs. Results showed that the carbon deposition process in stainless-steel tubes was relatively insensitive to fuel type or test condition. The deposition rates were comparable for all fuels and none of the stainless steel test pieces showed any signs of corrosion. For tests conducted with copper tubing, the sulfur content of the fuel had a significant impact

on both the condition of the tube wall and carbon deposition rates. Carbon deposition rates for the lowest sulfur fuels (2 ppm) were slightly higher than those recorded in the stainless-steel tubes with no corrosion observed on the inner wall surface. For fuels with slightly higher sulfur content (25 ppm), nodules that intruded into the flow area were observed to form on the inner wall surface. These nodules induced moderate increases in tube pressure reduction. The highest sulfur content fuels (400 ppm) produced extensive wall pitting and dendritic copper sulfide growth that was continuous along the entire tube wall surface, resulting in an inability to maintain flow rate owing to rapidly increasing test section pressure drops. Accompanying this corrosion were carbon deposition rates an order of magnitude greater than those observed in comparable stainless-steel tests. The results of this investigation showed that trace impurities in fuels (i.e., sulfur) can significantly impact the carbon deposition process and produce unacceptable corrosion levels in copper-based structural materials.

In the regeneratively cooled combustion chambers of liquid rocket engines using hydrocarbon fuels, coking occurs as the wall temperature increases, which results in coke deposition on the wall of cooling channels. This phenomenon reduces the cooling capability of the coolant, which finally causes damage to the combustor by overheating of the chamber wall. An electrically heated tube was used to simulate a regeneratively cooled channel and investigate the compatibility of copper alloys with hydrocarbon fuel Jet A-1 [73].

Parameters identified or suggested to influence fuel thermal stability and deposit formation include overall fuel chemical composition, specific fuel constituents such as additives (beneficial) and contaminants (detrimental), the effect of compositional variability on system-level cooling performance, primary fluid, and thermal conditions e.g., pressure, surface temperature, etc., and surface material composition and treatment. The need for an experimental approach capable of rapid, multi-parametric investigations of these and other factors influencing fuel thermal performance and cooling capability was addressed. Standard test methods existing a decade ago were incapable of achieving the very hot operating environments of cooling systems for advanced engines, and operational thermal stability tests are often accompanied by high associated costs and relatively long turnaround times. Under a collaborative research and development effort conducted by the AFRL and Johns Hopkins University/Chemical Propulsion Information Analysis Center, a rocket fuel thermal stability experiment has been designed and constructed in order to allow rapid assessment of fuel thermal integrity. It was hoped that this test will eventually qualify as an apparatus around which a standard method for thermal stability can be developed. The CRAFTI (Compact Rapid Assessment of Fuel Thermal Integrity)-based apparatus may be included in future fuel specifications as a thermal performance requirement.

The US Air Force (USAF) started an Aerospace Fuels Quality Test and Model Development program to identify conditions in kerosene fuels that may negatively impact or even jeopardize cooling system performance and reliability owing to compositional variations of fuels meeting existing specification limits and to mature and refine fuel

quality assurance practices for rocket-grade kerosene [74, 75]. Another objective was to develop predictive models correlating fuel composition with observed behavior in a cooling channel. An experimental apparatus was designed and constructed for the purpose of evaluating the effects of fuel purification technologies on thermal stability and material compatibility. This CRAFTI method was modified and extensively characterized under the AF project. In this versatile convective heat transfer experiment, fuel is pressurized by a positive displacement dual-syringe pump and flows through an ohmically heated test article, a tube. Electrical current is maintained via control of the dual power supplies, resulting in constant power during the test. Backpressure is held constant by an electropneumatically controlled dome loaded backpressure regulator. Downstream heat exchangers in series cool the effluent fuel to safe levels prior to sampling. The experiment is conducted in vacuum to reduce heat loss to surroundings, minimize oxidation of test article surfaces, and isolate the operator from potential hazards. Combined control of fuel flowrate, test article geometry, and supply power defines surface temperature profile, which in turn determines fuel exit bulk temperature. Recorded data include flow rate, power supply current and voltage, fuel inlet and exit bulk temperature, fuel pressure, and test article outer surface temperature, measured at 1.3-cm (0.5-in.) increments. To demonstrate overall CRAFTI repeatability, a series of ten runs was conducted using a specific RP-2 fuel under standard test conditions over a period of approximately 1 year. These runs were interspersed among nearly 50 others, many of which employed relatively high sulfur and aromatic content fuels. The ability of CRAFTI to reproduce carbon deposit behavior after a full year of testing with a variety of special blends, treated fuels, and worst case formulations, without full disassembly or extensive cleaning, indicated its excellent potential as a standard test method. Additional hydrocarbon fuel characterization was done using GC  $\times$  GC-TOFMS (time-of-flight mass spectrometry) with a reverse column configuration to enhance separation and optimize selectivity for the 19 fuel samples evaluated. In this configuration, the first dimension column had a polar stationary phase and the second dimension column had a non-polar stationary phase.

Based on results obtained with the CRAFTI apparatus, a Thermal Integrity Index was proposed as the quantifiable measure of fuel thermal stability for a future specification test. Additional discussion of results obtained with this apparatus is presented in subsequent sections on specific kerosene fuels.

### 2.8.3 Radiolysis of Kerosenes

One-hundred-milliliter samples of RP-1 generate 50.3 mL of radiolytic off-gas (measured at 298 K and 101 kPa (25°C and 1 atm)) when irradiated to  $8.5 \times 10^6$  rads with gamma rays [76]. When approximately 5 mass-% of an efficient, olefinic, free-radical scavenger was added to the samples, the off-gas volume produced by RP-1 fuel was reduced by 18.7% whereas those of hydrazine and Hydyne fuels were not reduced. These scavenging effects show that RP-1 fuel decomposes radiolytically by both free-radical

(18.7%) and molecular mechanisms, and that hydrazine and Hydryne fuels decompose entirely by a molecular or ionic mechanism. See also [77].

#### 2.8.4 Specifications for Kerosenes

Because commercially used liquid hydrocarbons are very rarely pure chemical compounds but are usually very complex mixtures of up to several hundred organic compounds, it is important to manufacture and procure fuels with reproducible properties. Military specifications specify the most important properties of the fuel mixtures, but still leave a wide range of variability from one producer to another. In 1944, the US first published specification AN-F-32 for JP-1, a kerosene jet fuel. This specification was changed to MIL-F-5616 in 1950. Many more specifications have been issued and updated in the interim.

Table 11 is an alphabetical summary with a brief description of the various kerosene fuels in the JP and RP series with number designations, some of which have been discontinued and are now only of historical interest. Although most of them are distillate ranges of naturally occurring petroleum, several are synthetic hydrocarbons with well-defined chemical structures, and although most of them were formulated to meet requirements of air-breathing jet engines, many have been used as rocket fuels because of their ready availability. However, one must remember that performance evaluation criteria for fuels for air-breathing jet engines and oxidizer-carrying rocket engines are quite different, the former going mostly by heat of combustion and density, whereas the latter need hydrogen-rich fuels to lower the mean molecular mass of the combustion products. The physical and chemical property requirements for hydrocarbons as rocket propellants and jet engine fuels are described in the Military Specifications:

Because kerosenes are mixtures and not a pure compound, their physical and chemical properties vary widely and are specified in industrial and military specifications, depending on the intended application. The most common fuel for jet engines is (was) JP-4. The most common fuel for rocket engines is (was) RP-1. Another summary table gives a partial list of kerosene specifications as they were in use in the 1960s. Table 12 gives the specification properties of some of the most commonly used kerosenes at that time. This table is now only of historical interest because many specifications have changed or have been canceled in the meantime. Specification limits for aerospace fuels are listed in Table 13. One of the older sources of information on foreign specifications for jet propellants is the book by Ragozin [78]. The foreign specifications for jet engine fuels have undergone many changes during the past century, just as the US specifications have evolved over time [79].

**Table 11:** Listing of kerosene designations.

| Designation      | Composition description                                                                                       | Specification <sup>a</sup> | Intended use                          |
|------------------|---------------------------------------------------------------------------------------------------------------|----------------------------|---------------------------------------|
| JP-1             | Narrow cut, low freezing point and high flash point                                                           | MIL-F-5616C (1944)         | Air-breathing jet engines             |
| JP-2             | Wider cut, unsuitable viscosity and flammability                                                              | MIL-F-5624C (1945)         |                                       |
| JP-3             | Wide-cut distillate fuel with a vapor pressure comparable with that of aviation gasoline                      | AN-F-58 (1947)             |                                       |
| JP-4             | MIL-F-5624A specification revision allowed the use of “cracked” materials in the formulation of JP-3 and JP-4 | MIL-F-5624C                | XB-70 bomber                          |
| JP-5             | High flash point kerosene. US Navy ship-board use                                                             | MIL-F-7914 (1952)          |                                       |
| JP-6             | Special fuel                                                                                                  | MIL-J-25656 (1956)         |                                       |
| JP-7             | Low vapor pressure and improved thermal oxidative stability. Low aromatics                                    | MIL-T-38219 (1970)         | SR-71 Hypersonic vehicle              |
| JP-8             | Lower vapor pressure than JP-4. Similar to commercial Jet A-1. It replaced JP-4 except in arctic regions      | MIL-DTL-83133A (1979)      | All land-based jet engines            |
| JP-9             | Ternary blend of Shelldyne-H, methylcyclohexane, and TH-MCPD                                                  | MIL-P-87107B (1979)        | ALCM                                  |
| JP-10            | exo-Tetrahydrodi(cyclopentadiene)                                                                             | MIL-P-87107B (1979)        | Cruise missiles, Tomahawk             |
| Jet-A and Jet-A1 | Commercial jet fuel                                                                                           | ASTM-D-1655                | Air-breathing jet engines             |
| RJ-1             | High-boiling-range kerosene                                                                                   | MIL-F-25558 (1956)         | Ramjet engines, Navaho cruise missile |
| RJ-4             | Tetrahydromethylcyclopentadiene dimer                                                                         | MIL-F-82522A (1971)        | Air-breathing ramjet engines          |
| RJ-5             | Hydrogenated dimers of norbornadiene, Shelldyne-H                                                             | Development                | Air-breathing ramjet engines          |
| RJ-6             | Mixture of RJ-5 and JP-10                                                                                     | Development                | Air-breathing ramjet engines. ASALM   |

Notes:

<sup>a</sup> Parentheses denote unit conversion from detail specification.

<sup>b</sup> Maximum value at –30 °F (–34 °C) is given.

<sup>c</sup> D56 is preferred method for Jet A.

<sup>d</sup> JP-5 also allows D5972; Jet A also allows D5972, D7153, and D7154.

<sup>e</sup> Jet A-1 value: –47 °C

<sup>f</sup> JP-5, Jet A: D4809, D3338, or D4529; RP-1/RP-2: D240

<sup>g</sup> JP-5: D3701; JP-8: D3701, D3343, or D7171; RP-1/RP-2: D3343

<sup>h</sup> Value provided is for JP-8 (MIL-DTL-831 33H).

<sup>i</sup> JP-5: D1266, D2622, D3120, D4294, or D5453; Jet A: D1266, D2622, D4294, or D5453; RP-1: D5453 or D5623; RP-2: D4045 or D5623

<sup>j</sup> Alternatively, D4952 can be used with sweet/negative result.

<sup>k</sup> JP-5, Jet A: 260 °C for 150 min; RP-2: 355 °C for 300 min.

### 2.8.5 Analysis of Kerosenes

A group-type analysis of hydrocarbons in a complex jet fuel may be more useful than attempting to analyze every component because such an attempt inevitably leaves a large portion of the fuel unidentified. Although it may be difficult to accurately determine the identity of a particular compound, that compound can often be classified as belonging to a group or compound class because of its chromatographic retention and mass spectral properties. Compound class quantitation is often capable of relating compositional information to fuel properties.

In rocket kerosenes, 150 to 200 components are usually detected. If one is lucky, 80% of these components can be identified by GC-MS, for instance, in the Russian Naftil fuel [81]. To construct correlations with the results of traditional methods of analysis, the identified compounds are usually split into groups according to chemical structure. Most often, three to eight groups are used.

Two-dimensional gas chromatography (GC  $\times$  GC) is a technique capable of providing this group-type separation and quantitation in jet fuels. This technique was used to examine a large set of fuels (Jet A, Jet A-1, JP-5, and JP-8, primarily) from petroleum sources and non-petroleum alternative sources, such as synthetic paraffinic kerosene [82]. By comparing results from GC  $\times$  GC analysis with those of established techniques and model compound studies, it was found that the accuracy of GC  $\times$  GC for this sort of group-type analysis is excellent.

#### 2.8.5.1 Assay Analysis of Kerosenes

Because liquid hydrocarbons very rarely are pure chemical compounds, but usually are very complex mixtures of up to several dozens of organic compounds, it is important to have uniform and accurate analytical methods to analyze fuels and obtain the same results, regardless of whether the analysis is done at the manufacturer, the intermediate dealer, or the end user. The task of the analytical methods is to verify the quality of the fuel with reproducible properties from batch to batch or from one supplier to another. Military specifications specify the most important properties of the fuel mixtures, but still leave a wide range of variability from one producer to another. Accurate and precise analytical methods help to narrow this range of variability. Many analytical methods for hydrocarbons as rocket propellants are described in the Military Specifications, for instance:

- Propellant, Kerosene, Grade RP-1, Spec MIL-P-25576
- Propellant, Jet Fuel, Grade RJ-1, Spec MIL-F-25558

In addition to verifying the assay and nominal properties, analytical methods also need to determine the amount of additives and possible undesirable contaminants.

#### 2.8.5.2 Distillation Curves for Analysis of Kerosene Mixtures

The boiling range of kerosene mixtures is quantified by fractionated distillation and MIL specifications specify the temperature ranges within which certain fractions of

distillate have to go over. These analysis methods are described in ASTM and API procedures, such as ASTM D86, ASTM D7345, or ASTM D2887.

Methods are sought that can provide a link between chemical composition and physical property information and provide the ability to calculate thermodynamic and transport properties for complex heterogeneous streams. One such technique was based on the advanced distillation curve (ADC) method, which separates complex fluids by distillation into fractions that are sampled, and for which thermodynamically consistent temperatures are measured at atmospheric pressure [83, 84].

### **2.8.5.3 Comparison of Different Grades of Kerosene**

A comparative evaluation of Russian kerosene and US RP-1 to support integration of Russian propulsion elements into the US space program followed a two-prong approach to provide better understanding of the differences. First, laboratory analysis provided insight into chemical and physical properties, and the theoretical rocket performance difference between the two fuels [85]. Second, hot fire testing provided performance and engine operational data with the two fuels. Analysis of the data showed three major differences: Russian kerosene is 3% more dense than RP-1, it has 21% less sulfur content, and the temperature rise with Russian kerosene through the cooling jacket is lower. No significant difference in the characteristic exhaust velocity,  $c^*$ , was found. The advantages and disadvantages of eventually using Russian kerosene in US vehicles and the impacts of using RP-1 with Russian engines can thus be evaluated.

### **2.8.5.4 Detection of Kerosene Vapors**

Because kerosenes have a low toxicity and relatively low volatility (compared with gasoline), there may be a relatively lax attitude toward monitoring the kerosene concentrations in the air of work areas. Only a few instruments for continuous monitoring of kerosene concentrations are in use.

A rocket kerosene vapor detector consisting of a light source, gas absorption cell, IR sensor, electric circuitry, and data collecting and processing system was designed based on non-dispersive infrared using an electrically modulated IR source and an IR filter [86]. The instrument had the advantages of great sensitivity, long life span, and rapid response. Kerosene vapors in contaminated soil and in the air above contaminated soil can be detected with a quartz crystal resonator on a piezo sensor [87].

### **2.8.6 Additives to Kerosenes**

Commercial hydrocarbon fuels may contain a wide range of different additives that are supposed to improve their performance for an intended application under given circumstances, but may interfere with their application as rocket propellants.

### 2.8.6.1 Anti-Icing Water Precipitation Additives

Alkanes are immiscible with water, but they possess a very small and often troublesome solubility for water. Hydrocarbons that have absorbed water from the air or have been exposed to water by accident may be saturated with water at room temperature. As soon as the temperature drops, water will come out of the solution and either form a puddle of water at the bottom of the tank or, worse yet, form ice crystals suspended in the fluid. Ice crystals in jet engine fuel or rocket fuel may clog filters and orifices. Often alcohols are added to hydrocarbon fuels to prevent water and ice precipitation. The water content must be analyzed and kept below a certain limit [88].

### 2.8.6.2 Antioxidants

Alkanes that are free from unsaturated compounds are stable in air. However, most commercially used hydrocarbon fuels contain varying percentages of unsaturated compounds that may autoxidize and polymerize, forming less soluble resins. Commercial grades of kerosene often contain anti-oxidants that are supposed to prevent resin formation.

Anti-oxidants may be added separately or in combination to the propellant in total concentrations not in excess of 8.4 lb of inhibitor (not including the weight of the solvent) per 1000 barrels of propellant (9.1g/100 US gal) in order to prevent the formation of gum:

- a. 2,6-di-*tert*-butyl-4-methyl phenol
- b. *N,N'*-di-*sec*-butyl-paraphenylenediamine
- c. 2,4-dimethyl-6-*tert*-butyl phenol
- d. 2,6-di-*tert*-butyl phenol

A metal deactivator, *N,N'*-disalicylidene-1,2-propanediamine, may be added in an amount not to exceed 2 pounds of active ingredient per 1000 barrels of propellant (2.2g/100 US gal).

A dye, methyl derivative of azobenzene-4-azo-2-naphthol, shall be added in an amount not to exceed ½ ounce (wt) per 1000 US gallons of RP-1 propellant. Dye shall not be added to RP-2 propellant.

Oxidation and polymerization inhibitors are hydroquinone or *tert*-butylcatechol. 4-*tert*-Butylcatechol is added as a stabilizer and an inhibitor of polymerization to butadiene, styrene, vinyl acetate, and other reactive hydrocarbons. It is 25 times more effective than hydroquinone for a polymerization inhibitory effect.

### 2.8.6.3 Corrosion Inhibitors

Santolene C, which was a phosphorus-containing dimer of linoleic acid, has been renamed/replaced by HITEC E515 (formerly Santolene C). HITEC E515 is a corrosion/wear inhibitor comprising dilinoleic acid and diamyl phenol acid phosphate in a kerosene-based hydrocarbon solvent. In December 2007, HITEC E515 corrosion inhibitor was replaced by HITEC E580, as HITEC E515 is no longer available.

#### 2.8.6.4 Static Dissipator Additives

Hydrocarbons are normally non-conductive to electricity. Flowing hydrocarbons in poorly grounded equipment may build up electrostatic charges and sparks from discharges may cause ignition in the presence of hydrocarbon vapors and air. Commercial grades of hydrocarbons may contain additives to provide marginal electrical conductivity to the liquid, just enough to prevent the build-up of electrostatic charges.

#### 2.8.6.5 Cetane Number Improvers

Kerosene that is intended to be used as diesel fuel may contain cetane number improvers, in particular in Arctic regions.

#### 2.8.6.6 Droplet Dispersion by Micro-Explosion Additives

Various types of kerosene-soluble organic azides and diazides, both aliphatic and aromatic azides, have been tested as additives to fuels (diesel engine fuels, jet engine fuels and rocket engine fuels) to enhance droplet break-up and dispersion in a flame zone. The types of azides used for this type of application have already been described in chapter “Azides and Azido Compounds.”

The combustion of such fuels with additives and the effect on droplet dispersion will be described in a future set of the *Encyclopedia of Rocket Propellants*, namely in *Encyclopedia of Non-Hypergolic Bipropellant Combinations*. The rates of fuel droplet evaporation can be improved by up to two orders of magnitude by the addition of organic azides. Diazidoalkane fuel additives were investigated as a method of improving the performance of LOX/RP-1 booster engines by causing microexplosions of evaporating fuel droplets. Compared with neat RP-1, the azide additives have greater fuel density and allow an increase in theoretical specific impulse for mixture ratios below 2.6. 1,10-Diazidodecane was used for the initial evaluation in four hot fire tests using subscale combustor hardware to determine the effect of diazidodecane on combustion performance. The density of diazidodecane is 20% higher than that of neat RP-1. 1,10-Diazidodecane is a clear liquid and is completely miscible with RP-1. See also [89, 90].

### 2.9 Handling of Kerosenes

#### 2.9.1 Facilities for Kerosene Storage and Transfer

The number one requirement for design of hydrocarbon storage and transfer facilities is the leak-proof design and the prevention of the escape of hydrocarbon vapors into the environment. In due consideration of the fire and explosion hazards in connection with hydrocarbons, all facilities should be properly grounded to prevent build-up of electrostatic charges and protected against lightning strike. Electrical equipment in the vicinity of hydrocarbon storage and transfer facilities must be spark-proof.

### 2.9.2 Fire Fighting of Kerosene Fires

Because hydrocarbons are not miscible with water and float on top of water while continuing to burn, water is not a very effective fire-fighting agent against hydrocarbon fires. Foam, carbon dioxide, and bicarbonate dust dry chemical fire extinguishers are more effective than water against hydrocarbon fires.

The most difficult fires to fight are those in launch vehicles that also contain an oxidizer. Launch mishaps are dramatic and there is very little one can do other than allowing the fuel to burn out and possibly cool surrounding structures with a water curtain. The water can have only a cooling action and will not extinguish the flames as long as there is oxidizer available.

## 2.10 Safety Properties of Kerosenes

The safety properties of jet fuels for the AF were reviewed with primary emphasis on JP-5 and JP-4 fuels. JP-5, a jet fuel that has a lower volatility than JP-4, was compared with JP-4 for AF jet aircraft operations. In the assessment of the data on the two fuels, special effort was made to determine whether there are 'fire-safety' advantages to be gained by the AF from the use of JP-5 instead of JP-4. From the study of pertinent technical information available and actual operational experience of the AF, it was suggested that use of a lower-volatility fuel such as JP-5 would have contributed little, if any, improvement in the AF flight safety record as of the mid-1960s. There was concern that the use of a fuel with lower volatility might reduce the military flight performance capability of certain types of AF aircraft. In spite of this critical assessment, the USAF switched from JP-4 to JP-8 or JP-8+100 during the following decades.

### 2.10.1 Flammability Limits of Kerosenes

Vapors of hydrocarbons mixed with air are flammable and potentially explosive. The exact flammable limits depend on the composition, and in particular on the boiling range of the kerosene blend.

### 2.10.2 Flash Points of Kerosenes

Flash point temperature is the lowest temperature where a fuel will give off sufficient vapors for ignition under ambient conditions. It is related to the lower flammability limit of fuels in air. There are two types of flash point measurement apparatus: open cup and closed cup. Flash point temperature is used by the National Fire Protection Association, and in the Hazardous Substance Classification Act to differentiate the relative fire hazards of fluids. The higher the flash point temperature, the less hazardous the fluid [91].

### 2.10.3 Pool Burning of Kerosene Spills in Air

It has been attempted to reduce the fire hazard of spilled kerosene by gelling it. Gelling would reduce the rate at which spilled hydrazine spreads over a large area and would reduce the rate of evaporation of spilled fuel. The speed of flame spreading over a gelled JP-4 oil-in-water emulsion held in a pool was observed by movie film recording [92]. The temperatures on and above the surface of the gel from the time when the flame front arrived to the time when it faded was measured with an array of thermocouples fixed in place. The flame-spreading velocity of JP-4 can be reduced by gelling down from one-tenth to one-twentieth of that of the original ungelled JP-4.

Flash points of oil-in-water gelled fuels with single and multiple components, and of commercial fuels were measured by the Tag Closed-Cup method and compared with those of neat, ungelled hydrocarbon fuels [93]. A dispersive-type infrared gas analyzer was used to measure the temperature dependence of the equilibrium vapor concentration of the emulsified fuel. Ignition aspects of an emulsified fuel pool surface were compared with those for neat liquid fuel. The effect of emulsification on the elevation of flash point was analyzed in terms of the reduction of fuel vapor pressure owing to solubilization in emulsion. Another finding was that by heating the surface locally, the emulsified fuel pool could be easily ignited, probably because of the considerable reduction of heat loss from the hot region as there existed no internal convection flow, even when the initial temperature of the emulsion was quite low and the flash point of neat hydrocarbon fuel was higher than the ambient temperature.

The influences of the initial temperature and the oil content of oil/water emulsions on flame-spreading velocity were investigated [94]. Characteristics of flame spreading upward and downward along an inclined pool were examined by altering the inclination angle and comparing results with those of a horizontal pool.

## 2.11 Toxicity of Kerosenes

### 2.11.1 Inhalation Toxicity of Kerosenes

Alkanes are not very toxic. Inhalation of air containing more than 1000 ppm alkane vapors can cause euphoric states of poisoning and at even higher concentrations the vapors will be narcotic.

Such high concentrations are not likely to be achieved with kerosenes used as rocket propellants because the vapor pressure is pretty low. Therefore, inhalation protection is usually not required when handling kerosenes at the tank farm or the rocket test site.

However, aromatic hydrocarbons, most of all benzene itself, are toxic. Inhalation or skin resorption of benzene can cause blood disorders and damage the bone tissues where the red blood cells are formed. Benzene is now categorized as a known human carcinogen. Acute and chronic inhalation toxicity, oncogenic exposures, and muta-

genic screening animal exposure tests were described and emergency exposure limits were established for JP-9, RJ-5, methylcyclohexane, and JP-10 [95].

### 2.11.2 Cutaneous Toxicity of Kerosenes

Careless spills of hydrocarbons on the skin may extract the skin grease and the skin will become brittle and cracked. In extreme cases vesicles may develop in the exposed skin. Liquid JP-4 spilled into the eyes causes instant irritation and lacrimation, most likely because of some of the additives in the commercially formulated jet fuel. Incidents of JP-4 spilled in the eye have not left any permanent damage. Nevertheless, wearing safety glasses where JP-4 is transferred under pressure is recommended.

### 2.11.3 Environmental Impact of Kerosene Spills

Kerosene spills on the ground cause ground water pollution and may kill some soil bacteria. Other bacteria can be enticed to digest hydrocarbons and used for bioremediation of kerosene spills.

Nutrients such as nitrogen and phosphorus are necessary for effective biodegradation of spilled hydrocarbons in the soil. These nutrient compounds are frequently injected into the contaminated subsurface to enhance *in situ* biodegradation. The effect of residual sub-surface hydrocarbon (kerosene) contamination on the transport of an electron acceptor ( $\text{NO}_3^-$ ) and a nutrient ( $\text{NH}_4^+$ ) was investigated [96]. Soil column experiments were conducted using uncontaminated and contaminated soil, and a one-dimensional solute transport model with multi-process non-equilibrium sorption was used to predict the breakthrough curves. The presence of kerosene contamination was found to cause an earlier breakthrough time for  $\text{NO}_3^-$  relative to the uncontaminated soil, which was predicted by the transport model. The exchange isotherm involving  $\text{NH}_4^+$  was not affected by the presence of kerosene.

## 2.12 Fuel Mixtures with Kerosenes

The kerosenes JP-4, RP-1 and others are good rocket propellants because they are readily available. The storability and ease of handling make them very attractive. The main disadvantage of kerosenes is that they are not hypergolic with most of the common oxidizers. The only oxidizers that are hypergolic with kerosenes are fluorine and some of the fluorine oxidizers such as chlorine trifluoride or chlorine pentafluoride. There have been numerous attempts to hypergolize kerosenes by adding hypergolizing additives to either the fuel or the oxidizer. Other additives to kerosenes were made with the intent to increase their heat of combustion (see Section 2.12.3) or improve their ignition properties (e.g., amine nitrates) [97].

### 2.12.1 Hypergolization of Kerosenes

There have been numerous attempts to hypergolize kerosenes by adding hypergolizing additives to either the fuel or the oxidizer or both. One hypergolizing additive to the fuel, unsymmetrical dimethylhydrazine (UDMH), has actually seen flight application.

#### 2.12.1.1 Hypergolization of Kerosene by the Addition of UDMH

Kerosene has been hypergolized by the addition of unsymmetrical dimethylhydrazine to render it hypergolic with red fuming nitric acid (RFNA) or white fuming nitric acid (WFNA). There were two types of UDMH/JP-4 blends, one with 17% UDMH and one with 40% UDMH, as specified by Specification MIL-P-26694B. JP-X Type I is a mixture of 60% JP-4 and 40% UDMH and was used in the BOMARC booster [98, 99]. The NIKE-AJAX missile fuel was JP-X Type II with 17% UDMH in JP-4 [4].

#### Physical Properties of Kerosene/UDMH Mixtures

The physical properties of JP-4/UDMH mixtures with 17 to 40% UDMH are summarized in chapter “Dimethylhydrazines.” Unsymmetrical dimethylhydrazine is only marginally miscible with JP-4. It is important that the fuel and the additive remain completely mixed over the entire range of service temperatures. The problem is that small quantities of water addition cause the binary solution to break into two phases, which is not acceptable and would prevent the missile from igniting when commanded to launch (similar phase separation problems are encountered with Gasohol in automobiles). For a mixture containing 17% UDMH in JP-4, only 0.2% water causes phase separation at 233 K (−40 °C). When the mixture contains 40% UDMH, it tolerates 1% water at 233 K. Mixtures containing 40 mass-% UDMH in JP-4 are more moisture tolerant, and will tolerate up to 5 mass-% water without phase separation at 233 K (−40 °C).

#### Chemical Properties of Kerosene/UDMH Mixtures

The compositions of JP-X mixtures were specified by Military Specification MIL-P-26694B – Propellant, JP-X (JP-4 + UDMH) [100]. These specifications covered three types of JP-X. The nominal composition limits and purity requirements of these three types of JP-X are listed in Table 14.

The ignition properties of this fuel with hypergolic oxidizers will be described in the forthcoming *Encyclopedia of Hypergolic Bipropellant Combinations*. Even smaller additions of UDMH to kerosenes (insufficient to achieve hypergolic ignition) improve the stability of combustion of kerosenes with WFNA or RFNA [101]. A fuel mixture containing 17 mass-% UDMH in JP-4 with the designation M-3 was used in the NIKE-AJAX Surface-to-Air-Missile [102, 103]. The mixture, containing 40 mass-% UDMH and 60 mass-% JP-4, had the designation JP-X.

**Table 14:** Composition limits and purity requirements of hypergolized kerosene per MIL-P-26694B.

| Constituent            | Distillation limit | Unit              | Type I      | Type II     | Type III      | Analytical method          |
|------------------------|--------------------|-------------------|-------------|-------------|---------------|----------------------------|
|                        |                    |                   |             |             |               |                            |
| JP-4 per MIL-T-5624    |                    | Mass-%            | 40 ± 1      | 17.0 ± 0.3  | 50.0 ± 2.0    | —                          |

### Analysis Methods for Kerosene/UDMH Mixtures

Because the water content of these mixtures had to be measured frequently to make sure the fuel would not segregate at low temperatures, a field method for the determination of water in M-3 and JP-X was developed. It was a gasometric method, based on the reaction of a fuel sample with an excess of calcium hydride. Calcium hydride would react with water and develop hydrogen gas, which was captured in a gas burette [104].

#### 2.12.1.2 Hypergolization of Kerosene by Suspension of Metal Hydrides

A very unusual method for hypergolizing kerosenes is the suspension of finely divided alkali metal hydrides. Alkali metal colloidal suspensions or alkaline earth metal hydrides do not dissolve in kerosene, but they are inert to dry hydrocarbons and can be stored under dry hydrocarbon oil indefinitely. Suspensions of alkali metal hydrides in kerosene are hypergolic with WFNA and have very short ignition delays. These suspensions are easy to prepare, and only a small percentage of hydride additives is needed [105]. It is a disadvantage that the hydrides settle within less than an hour if the kerosene is not gelled. It is not practical to continuously stir the fuel just prior to launch to keep the particles in suspension. If the kerosene/hydride suspension is not gelled or agitated, the powder would settle at the bottom of the tank. The first slug of fuel drained from the tank would consume all the hydride. It would achieve the first ig-

nitition, but the engine may not be restartable or the remainder of the fuel may develop combustion instabilities. In addition, the hydride sludge may clog pumps or orifices.

A student group at the University of Stuttgart, Germany, tested small rocket engines with WFNA and sodium hydride suspensions in kerosene, achieving hypergolic ignition. Commercial kerosene usually contains some moisture, which would deactivate the sodium hydride. Pre-drying the kerosene with calcium hydride, decanting it, and then adding the sodium hydride slurry were recommended. An attempt was also made to slow down the settling of the sodium hydride suspension by increasing the density of the fuel.

### 2.12.2 Gelled Kerosene (Without Suspended Solids)

Most of the work on gelled kerosene has been done to suspend metal or metal hydride powder to improve the fuel properties of kerosene by making them hypergolic with nitric acid or to increase the specific impulse. Some work has been done on gelling kerosene as a means of reducing leakage in case an aircraft tank gets punctured by shrapnel while in battle. Much of this work is related to the work on gelled jet fuels to reduce the fire hazard in case of airplane crashes on the ground. As opposed to a Newtonian fluid, for a non-Newtonian liquid the viscosity  $\eta$  is dependent on the applied shear rate  $\dot{\gamma}$ . For the characterization of Newtonian and non-Newtonian fluids without a yield point, the power-law model (Ostwald–de Waele model) is the most common correlation:

$$\eta = K\dot{\gamma}^{n-1} \quad (1)$$

where  $K$  is the consistency index and  $n$  is the power law index of the fluid. For  $n = 1$  Eq. (1) describes a Newtonian fluid. However, shear thinning (thixotropic) behavior is given for a power-law index  $0 < n < 1$ , and shear thickening (dilatant behavior) for  $n > 1$ .

There are numerous publications on the rheology of gelled liquids, in particular those exhibiting thixotropic behavior (“non-Newtonian fluids”), which relate to all gelled propellants, but very often include work on gelled kerosenes or gelled ethanol [106–110].

The viscosity of thixotropic fuels is dependent on the shear rate. Pumping gelled propellants requires higher feed pressures than pumping ungelled propellants. Injection of gelled propellants into combustion chambers results in different modes of droplet break-up.

Description of properties of gelled kerosene and metallized gelled kerosene in this chapter of the book would normally be restricted to selection of gelling agents, preparation of gels, viscosity and rheology of gels, droplet evaporation, segregation under high acceleration, and storage life (limited by “syneresis”) of gels. In several instances these publications deal not only with the aforementioned topics but also proceed to burning the gelled kerosene either in a laboratory apparatus or in a jet or rocket engine. Several publications in this dual-topic category are therefore discussed both here

and will eventually reappear in *Encyclopedia of Non-Hypergolic Bipropellant Combinations*, for the combustion of gelled propellants.

A numerical algorithm was developed for the steady, incompressible, isothermal, laminar flow of a power-law, shear-thinning gel propellant in a converging injector [111]. Such equations would apply to all gelled propellants, but would most likely be used for gelled kerosenes first. The effect of the injector geometry and the flow rate on the velocity and viscosity fields was evaluated for different gelled propellants. In comparison with a straight-passage injector, a convergent one can produce an additional decrease in the mean apparent viscosity of the fluid. The mean apparent viscosity decreased significantly by increasing the convergence angle of the injector. In general, increasing the gel flow rate resulted in a decrease in the mean apparent viscosity of the fluid. Increasing the gellant content of gel propellants resulted in an increase in the fluid viscosity, which decreased when the gel flowed through the injector. Gels of different gellant content that flow through the same geometry injector exhibited similar relative reduction in viscosity.

In bipropellant systems, in particular those with pressure-fed propellants, it is desirable that both oxidizer and fuel should have similar rheological properties, although an exact match is not required [112]. Gelled JP-8 and RP-1 fuels have been used to study the rheological behavior of gelled hydrocarbons using 4–7 mass-% of fumed silica as the gelling agent [113]. Viscosity, stability, thixotropic behavior, and the viscoelastic properties of the gel through their storage and loss moduli were measured as a function of the amount of gelling agent added. Differential scanning calorimetry measurements showed only a slight influence of the amount of gelling agent on the enthalpy of vaporization of the gels. The ungelled hydrocarbons had a higher enthalpy of vaporization than the gels.

Isolated fuel droplets were held in place to investigate experimentally the combustion process of gelled propellants under normal gravity conditions in air [114]. Phase separation of the gel propellant components leading to bubble nucleation, vapor jetting, and microexplosions were found to be the main phenomena involved during the combustion period. The effect of gellant concentration on the burning rate constant as well as flame structure was examined. The burning rate constant decreased with an increase in the gellant concentration. The decrease in the calorific value of the increasing gellant concentrations was most likely one of the reasons for this variation. The flame exhibited a triple flame structure for all the cases for both zones with free radicals as well as visible luminous flames.

Collision of two droplets is a fundamental form of droplet interaction in the spraying droplet flow field in the injector of rocket engines. An axi-symmetric form of the Navier–Stokes equations based on the *volume of fluid* method was used to study the central collision mechanism of two gel droplets with equal diameters and to track the evolution of the gas–liquid free interface [115]. The model was validated by experimental results on Newtonian liquids. Phenomena of rebound, coalescence, and reflexive separation of droplets after collision were investigated, and structures of the compli-

cated flow fields during the collision process were analyzed. Results showed that the maximum shear rate appears at the point where the flow is redirected and accelerated. Rebound of droplets is determined by the Weber number and viscosity of the fluid. It was concluded that the gel droplets are easier to rebound than the base fluid droplets. The results showed that the alternating appearance along with the deformation of droplets in the radial and axial direction is the main characteristic of the droplet coalescence process. The reflexive separation process of droplets can be divided into three distinctive stages including the radial expansion, the recovery of the spherical shape, and the axial extension and reflexive separation. The maximum deformation of droplets appeared in the radial expansion stage.

In order to investigate the evaporation characteristics of a single kerosene gel droplet, an isolated kerosene gel droplet with an initial diameter of ~2mm was suspended at the welding point of a thermocouple wire, and was suddenly exposed to an elevated temperature (within the range 373–773 K = 100–500 °C) at atmospheric pressure (0.1MPa) under normal gravity [116]. The droplet-changing process was recorded by a high-speed imaging system. The results indicated that the evaporation process of a single gel droplet can be divided into three stages: **(1)** the stage of the evaporation of kerosene; **(2)** the stage of the gellant layer formation; **(3)** the stage of the swelling of the gellant layer and microexplosions taking place. Several unique phenomena, such as bubble nucleation, gellant layer formation, disruption of gellant layer, and slight explosion of the initial droplet, were observed. The initial evaporation rate of kerosene gel resembled the evaporation rate of a pure kerosene droplet at a relatively low temperature. However, micro-explosions would occur once the environmental temperature exceeded the boiling point of kerosene.

### 2.12.3 Metal Suspensions in Kerosenes

Ever since the first tests with liquid rocket engines, there have been numerous attempts to improve the performance of LOX/kerosene by the addition of metal powders that have a high heat of combustion. Some of the first tests of this kind actually firing a LOX/kerosene/Al rocket engine were conducted by the famous rocket pioneer Eugen Sänger in Austria in the 1930s [117, 118]. A term coined for these suspensions (English synonym: slurries) in German was “Kerosol” which may be somewhat misleading because nothing was dissolved.

The performance of kerosene as a fuel for bipropellant combination can be enhanced by suspending finely distributed metal powders, preferably aluminum or beryllium. In order to prevent the metal powder from settling during storage, the mixture has to be gelled. The amount of metal that can be added is limited by the increasing viscosity of these blends, making them hard to pump and inject into a combustion chamber [119, 120].

In addition to using metallized kerosene slurries in rocket engines, these fuel mixtures were also evaluated in air-breathing ramjets or in afterburners. It would be diffi-

cult to use them in turbocompressor jet engines because the condensed exhaust products (mostly aluminum oxide) would sandblast the turbine blades and would deposit in undesirable locations. Metallized kerosene slurries for ramjets (no moving parts) and rocket engines were developed at NASA in the US and at LRBA in Vernon (France). It is difficult to achieve complete combustion of metal particles within the short dwell time in the combustion zone. While burning, many metal particles become coated with a layer of high-melting oxides that impede further combustion. The combustion of metal slurries in hydrocarbons will be discussed in more detail in *Encyclopedia of Non-Hypergolic Bipropellant Combinations*.

A compilation of physical and performance data for both neat and heterogeneous propellants in bipropellant rocket and air-augmented rocket applications with emphasis on the air-augmented cases contained physical and thermochemical properties for the neat liquid fuels and oxidizers, including boiling point, freezing point, density, enthalpy of formation, vapor pressure, critical properties, enthalpy of vaporization, viscosity, and specific heat [121]. Physical properties for the heterogeneous fuels included composition, density, graphs of shear stress versus shear rate and temperature, mechanical and thermal stability, specific heat, thermal conductivity, and enthalpy of formation. The performance applications featured bipropellant operation, augmented boost, an air-augmented cruise case in a ducted rocket configuration, and the ramjet mode of operation. The results of the theoretical calculations on performance included maximum density, specific impulse, bulk density, mixture ratio, air ratio, and burnout velocity.

Stable suspensions of aluminum and boron carbide in various hydrocarbons have been prepared for use as ramjet fuels and fundamental chemical and physical properties of these suspensions related to Navy storable propellant criteria were measured [122]. Total burning times of concentrated dust particle flames of carbon, boron, boron carbide, and aluminum at atmospheric pressure in air were examined and compared, and the implications of these dry burning rates with respect to the combustion efficiencies of metal particles in gelled fuels in ramjet missiles were discussed.

In spite of ongoing efforts to develop metallized kerosene slurries, the efforts that have been going on for more than half a century have not produced any flight application or fielding of metallized kerosene rocket or air-breathing propulsion systems and it is doubtful they ever will. Being fully aware of these many futile attempts to get metallized hydrocarbon gels to fly, an attempt has been made here to gather information from the literature and assemble it in a useful format just to prevent the mistakes of the past from being repeated by future generations of propellant chemists. Our collection is incomplete. There are so many references on metallized hydrocarbon and hydrazine, methylhydrazine (MMH), or UDMH gels that they would fill a book by themselves.

There is another chapter on the combustion of metallized kerosene slurries in the forthcoming *Encyclopedia of Non-Hypergolic Bipropellant Combinations*. Owing to the

higher viscosity and two-phase nature of these gels, injection and atomization of fuel sprays in a combustion chamber are difficult tasks.

### 2.12.3.1 Metal Selection for Kerosene Slurries

The additives with high heats of combustion are boron, aluminum, and possibly magnesium. Beryllium would be a good additive if it were not for the toxicity. The solids loading of the metallized gels cannot exceed 60% because such gels could no longer be pumped because of their high viscosity. Usually, smaller metal loadings, within the range 10–20%, are sufficient to achieve a significant improvement of performance.

Suspending metals in kerosene not only makes them more energetic, it can also make them hypergolic with nitric acid as the oxidizer. Finely suspended lithium metal makes kerosene hypergolic with WFNA or RFNA [123].

### 2.12.3.2 Nano-Metals Suspended in Kerosene

In the most recent decade, nano-metals have received a substantial amount of interest for various propulsion applications in gelled and solid propellants. The advantages of aluminum as a nano-metal (“Alex<sup>®</sup>”) over regular vacuum-dispersed aluminum are more complete combustion and higher burning rates.

The heat of combustion of every ingredient by itself and a mixed nano-aluminum/kerosene gel system was measured [124]. It is surprising that the mass-specific heat of combustion of the nano-aluminum/kerosene gel system decreased with an increase in nano-aluminum powder content in the gel system. The reason is that the heat of combustion of nano-aluminum powder is lower than that of kerosene. But the density and volume-specific heat of combustion of the systems increase with an increase in nano-aluminum powder content.

Nano-aluminum suspensions in kerosene with a gelling agent were prepared by means of electromagnetic stirring and ultrasonic agitation [125]. With increasing nano-aluminum powder content, the required amount of gellant to form a stable nano-aluminum/kerosene gel system decreased. When the content of nano-aluminum powder was >6%, no further gellant was needed, which indicated that nano-aluminum powder itself acted as a gellant. However, the normal micron-sized aluminum powder cannot act as a gellant. The ultrasonic agitation of nano-aluminum in kerosene achieved a better suspension than electromagnetic stirring. The optimal dispersion time needed to form a nano-aluminum-kerosene gel was 8–10 min by means of ultrasonic agitation.

### 2.12.3.3 Gelling Agents for Kerosene Slurries

A wide range of gelling agents has been evaluated as a means of suspending metal powders in kerosenes and other liquid fuels.

In the early years of rocket propulsion in the 1930s, Sanger tested metal salts of fatty acids (“metal soaps”), latex rubber, Oppanol<sup>®</sup> and other polymers in order to slow down the sedimentation of metal particles. Oppanol<sup>®</sup> B (Producer: BASF)

is a series of medium- and high-molecular-weight polyisobutenes, with an average molecular weight between 40000 and 4000000.

THIXCIN R (Producer: Elementis in the UK) is a non-hygroscopic organic derivative of hydrogenated castor oil that imparts a high degree of thixotropic thickening in mineral and silicone oils, as well as low-polarity aliphatic solvents. Thixatrol ST is an amide of ricinolic acid. These gelling agents need extra time for swelling, deagglomeration, and activation before a stable gel is formed. Other gelling agents are metal soaps, salts of long-chain carbonic (“fatty”) acids such as aluminum octanoate. Even without the addition of suspended metal particles, there may be some incentive to use gelled hydrocarbons, mostly to reduce spillage in the case of a leak and to reduce slosh in the case of launch phase instabilities.

A study of the physical properties of slurries of commercial magnesium, aluminum, and boron powders (particle size 10–66  $\mu\text{m}$ ) suspended in MIL-F-5624-grade JP-3 fuel used metal soaps (magnesium stearate or aluminum octoate) to stabilize the slurries [126]. Physical properties measured included density, apparent viscosity, apparent surface tension, storability, and fuel-flow characteristics. Several of the prepared slurries had physical properties acceptable for combustion research and limited flight use.

Fumed silica, also known under the trade name Cab-O-Sil<sup>®</sup>, is a useful gelling agent for fuels as well as oxidizers. The rheological behavior of gelled JP-8 turbine fuel and gelled rocket propellant RP-1 with fumed silica as a gelling agent was measured and the optimal gel mixing process, gel stability, and rheological parameters showed a significant influence of the added silica amount [127, 128].

The rheology and droplet-burning behaviors of JP-8 and RP-1 gelled with fumed silica were compared with those of MMH gelled with hydroxypropyl cellulose [129]. Droplets of gelled MMH burning in air swelled and had a flexible droplet surface, whereas burning kerosene droplets gelled with fumed silica had a rigid silica structure that remained unburned.

#### 2.12.3.4 Gelled Metallized Kerosene Slurries

There are countless patents on metallized gelled fuels, describing various gelling agents and stabilizing additives. Many of those patents are purely speculative and repetitive, and probably very few were ever put into practice (Table 15). It is obvious that the patent examiners were not trained propellant chemists and that they should have rejected many of these vague patents.

**Table 15:** Summary of patents on metallized kerosene slurries.

| Author                 | Year | Metal(s)  | Gelling agents           | References |
|------------------------|------|-----------|--------------------------|------------|
| Martin                 | 1961 | Mg, Al    | Polyethylene             | [130]      |
| Whaley                 | 1961 | B, Al, Mg | Polyethylene, oleic acid | [131]      |
| White, Chin, and Jones | 1966 | Al, Mg    | Bentone 34               | [132]      |

The higher the density of the hydrocarbon in which the metal particles are suspended, the less likely the metal particles are to settle out of suspension in a gravity field, and the less gelling agent would be needed. In addition to conventional kerosenes such as JP-4 or RP-1, high-energy, high-density hydrocarbon fuels have also been evaluated for gelled metallized fuel formulations and the energy density of those fuels can be increased further by suspending metals or boron in these fuels. Gelled high-density fuels with high volumetric heating values are of interest for extending the range of air-breathing tactical ramjets. High-density liquid hydrocarbons containing suspended metal powders are of interest for applications in air-launched, volume-limited missiles. These fuels must exhibit suitable physical properties over a wide temperature range, long-term storage stability, low toxicity, a very low degree of manufacturing and handling hazard, and very high volumetric heats of combustion.

#### 2.12.3.5 Gelled Boron Kerosene Slurries

Boron-hydrocarbon slurry fuels were prepared, containing 50–60 mass-% of boron powder of 1- $\mu\text{m}$  average particle size in JP-4 and JP-5 fuels [133]. The boron-hydrocarbon mixtures were fluidized by glycerol sorbitan laurate, a surface-active agent, and stabilized by aluminum octoate, a gelling agent. The useful life of a slurry was approximated by the age at which the settled portion of the slurry could no longer be readily redispersed. Satisfactory stability for up to 6 months was observed for several slurries, but some of these slurries were still in a satisfactory physical state after 6 months. The viscosity at low rates of shear varied with the age of the slurry, but did not follow the same pattern for all slurries. The apparent viscosity of the slurry at a low rate of shear increased with increasing boron and aluminum octoate concentrations, but decreased with increasing concentration of glycerol sorbitan laurate. The JP-5 slurries seemed to exhibit a slightly higher viscosity than the corresponding JP-4 slurries, probably because of the higher density of the JP-5.

Surface-modified boron nano-particles were added to jet fuel JP-10 with trioctylphosphine oxide as the stabilizer, which inhibited particle contact and agglomeration [134]. After 6 weeks, a suspension with 12.7 mass-% boron nano-particles was still completely dispersed in the fuel. The addition of 12.7 mass-% boron increased the density and volumetric energy from 0.93 g/ml and 39.4 MJ/l to 0.98 g/ml and 43.4 MJ/l respectively. The suspension flowed freely like liquid fuel and had relatively low viscosity at low temperatures. Boron-kerosene slurries have been tested in ramjet combustors (This may be included in a future *Encyclopedia of Non-Hypergolic Bipropellant Combinations*).

#### 2.12.3.6 Gelled Magnesium Kerosene Slurries

As magnesium is a relatively inexpensive material and in air-breathing engines it has a greater heat of combustion per pound of air than aluminum, the experimental investigation of magnesium slurries has progressed farther than those of either aluminum

or boron. NACA conducted numerous experiments with magnesium slurries, describing the preparation and stabilization of the gels, combustion experiments, and showing examples of pumps, valves, and combustion chambers for metallized kerosenes [135].

A study of the effect of magnesium particles of various equivalent diameters on the apparent viscosity, sedimentation rate, and redispersibility of petrolatum-stabilized magnesium-JP-4 slurries used powders with equivalent diameters of 2.8, 3.7, 7.2, 9.3, 12, and 14.8  $\mu\text{m}$  [136]. As the average particle size of metal was increased from 2.8 to 14.8  $\mu\text{m}$  in slurries containing the same concentration of magnesium, minimums were observed in the apparent viscosity–magnesium concentration curves. Data were also presented showing the effect of various magnesium concentrations with constant particle diameters on these physical properties.

Kerosene JP-4/Mg slurries have been prepared and tested in rocket engines. Ball-milling 200-mesh magnesium powder in JP-4 containing a wetting agent resulted in a useful metallized slurry [137]. Flight testing of magnesium slurries was done in ram-jets [138].

Attempts have been made to reduce the viscosity and improve the pumpability of gels by adding surfactants [139]. For example, the apparent viscosity of a slurry consisting of 49% Mg in JP-1 could be reduced by using 3–5% of a surfactant additive.

In a study of the use of surface-active additives to reduce the viscosity of thick slurries consisting of 50% by weight of 1.5- $\mu\text{m}$  magnesium powder in *n*-decane, it was found that as the slurry became increasingly fluid the magnesium tended to settle more quickly [140]. The viscosity of the slurry was dependent on the concentration and composition of the additive. Removal of part of the moisture (or perhaps other adsorbed components of the air) from the magnesium powder prior to the addition of the *n*-decane resulted in a product with lower viscosity. A complete summary of effects of metal loading, particle size, and additives on viscosity and settling rates of magnesium–kerosene slurries, illustrated with several graphs, was provided in Barnett et al. [141].

Slurry fuels containing extremely small particles of magnesium were prepared by concentrating the dilute slurry product resulting from the shock-cooling of magnesium metal vapors with a liquid hydrocarbon spray [142]. Ninety-five percent by weight of the solid particles formed by this process passed through a 100-mesh screen. The screened product was concentrated by means of a bowl-type centrifuge from 0.5 to more than 50% by weight of solid content to form an extremely viscous, clay-like mass. By the addition of a surface-active agent, this viscous material could be converted into a pumpable slurry fuel. The high viscosity and the two-phase composition of magnesium slurries make it difficult to achieve good atomization and small droplet spray patterns when injected into a combustion chamber [143]. The dielectric constant of metal slurries can be measured as a method for measuring the metal loading and the settling rate of metal slurries in kerosene [144].

### 2.12.3.7 Gelled Aluminum Kerosene Slurries

#### Micron-sized Aluminum–Kerosene Slurries

Butyl-decyl-thiomethylphosphonate was used as a gelling agent for dispersing aluminum in a thixotropic fuel [145]. In an effort to formulate and characterize the properties of Al/RP-1 and non-metallized RP-1 gelled propellants for rocket propulsion systems, 24 different compositions of gelled fuels have been formulated with 5 and 16  $\mu\text{m}$  atomized aluminum powder in RP-1 [146]. The total solids loading in the propellants varied from 5 to 60 mass-%. Storage tests evaluating the stability and rheological characteristics of the fuels showed that the physical separation of the solids occurred in fuels with less than 50 mass-% solid concentration.

The performance of kerosene as a fuel for bipropellant combination can be enhanced by suspending finely distributed metal powders, preferably aluminum or beryllium. In order to prevent the metal powder from settling during storage, the mixture has to be gelled. The amount of metal that can be added is limited by the increasing viscosity of these blends, making them hard to pump and inject into a combustion chamber [119, 120]. Fumed silica Cab-O-sil, ethylcellulose, methylcellulose, agar agar, polypropylene glycol, hydroxymethyl cellulose, carboxymethyl cellulose, and clay were tested as gelling agents for kerosene and UDMH. Agar agar or methylcellulose gave no gelation at 7.5% in kerosene. Cab-O-sil and polypropylene glycol at 7% gave only partial gelation. An organophilic clay complex with polypropylene glycol gave a gel that could be loaded with 30 or 40% 15- $\mu\text{m}$  size aluminum powder. The viscosity values deduced from a Brookfield viscometer and from a rheogram against shear rate or rotations per minute showed that metallized kerosene gels containing 30 and 40% aluminum showed a drastic decrease in viscosity with an increase in shear rate or rotations per minute. Viscosity values had a decreasing trend with increase in temperature, though not very marked.

Aluminum powder made by explosively vaporizing electrically heated aluminum wire (Alex) can be gelled in kerosene using fumed silica as the gelling agent [147]. The metal loading and the higher viscosity make it difficult to achieve small droplet size when injecting metallized gelled kerosenes into a rocket combustion chamber. The spray characteristics of an aluminized gel were tested with an impinging jet like-on-like injector [148, 149].

JET A-1 (JP-8) gels were prepared using inorganic (fumed silica) and organic (Castor oil derivatives and aluminum octanoate) gelling agents [150, 151]. The main parameters varied were dissolver disk rotational speed, dissolver diameter, gellant particle size, gellant content, and temperature history of gelation. Gel stability was investigated in conventional and optical centrifuge tests with rotor speeds up to 3000 rpm at accelerations up to 2500 g, and it was shown that all the aluminum/kerosene gels were stable below 100 g. Viscosity measurements were performed using rotational cone and plate viscosimeters. All gels showed strong shear-thinning behavior. The results could be fitted to existing viscosity laws and were used to compute the predicted pressure drop in gelled propellant rocket injectors and propellant feed lines.

The spray patterns of aluminized gelled Jet A-1 kerosene were examined as a function of shear rates and metal content [152]. Decreasing dynamic shear viscosity values were found with increasing shear rates and increasing viscosity values with increasing Al content. A high-speed camera study of the atomization behavior of the gels with a doublet like-on-like impinging jet injector under ambient conditions with varying pressure and temperature showed different break-up modes of the jets. Low-density decane-based slurries were prepared with powders of mechanically alloyed Al/Li, nano-composite 2B+Ti, and pure aluminum [153].

The combustion of metallized hydrocarbon slurries will be discussed in more detail in a future volume of the *Encyclopedia of Rocket Propellants*, namely in *Encyclopedia of Non-Hypergolic Bipropellant Combinations*.

### Nano-Sized Aluminum-Kerosene Slurries

Nano-aluminum has been extensively studied as an additive to solid propellants, and can also be used as an additive to kerosene. This is probably mostly done for the use of metallized kerosenes in ramjets, but will also be useful for metallized kerosenes in rocket engines. Addition of nano-aluminum to kerosene would not only increase its volume-specific heat of combustion but also shorten the ignition delays in burners. In a ramjet, poor mixing of fuels and air and insufficient flame holding can cause loss of stability and flameout.

The evaporation characteristics of kerosene droplets containing dilute concentrations (0.1, 0.5, and 1.0 mass-%) of ligand-protected aluminum nanoparticles (n-Al) suspended on a silicon carbide fiber were studied at different ambient temperatures (673–1073 K = 400–800 °C) [154]. The evaporation behavior of pure and stabilized kerosene droplets was also examined for comparison. The results showed that at relatively low temperatures (673–873 K = 400–600 °C), the evaporation behavior of suspended kerosene droplets containing dilute concentrations of nano-Al was similar to that of pure kerosene droplets and exhibited two-stage evaporation following the classical  $d^2$ -law. However, at relatively high temperatures (973–1073 K = 700–800 °C), bubble formation and micro-explosions were observed, which were not detected in pure or stabilized kerosene droplets. For all nano-Al suspensions, regardless of the concentration, the evaporation rate remained higher than that of pure and stabilized kerosene droplets within the range 673–1073 K = 400–800 °C. At relatively low temperatures, the evaporation rate increased slightly. At very high temperatures (700–800 °C), the melting of nano-Al particles led to substantial enhancement of evaporation. The maximum increase in the evaporation rate (57%) was observed for the 0.5% nano-Al suspension at 1073 K (800 °C).

The effects of high ambient temperatures and various concentrations of nanoparticles on the auto-ignition and combustion characteristics of heptane-based nano-fluid droplets were examined using single, heptane ( $n\text{-C}_7\text{H}_{16}$ ) droplets containing 0.5, 2.5, or 5.0 mass-% of nano-Al mounted on a silicon carbide fiber that was exposed to a rapid increase in temperature, (from room temperature to temperatures within

the range 873–1123 K = 600–850 °C) at atmospheric pressure, and the auto-ignition and combustion characteristics were observed [155]. The ignition delay, burn rate, and combustion characteristics of pure and stabilized heptane droplets were also examined for comparison.

Nano-powder materials and dispersants were evaluated for enhanced kerosene fuels with higher particle loading fractions [156]. All commercially available nano-sized aluminum particles examined were found to be unsuitable in the as-delivered state for making metallized gelled kerosene. A high fraction of the particles were in the form of undispersable permanent agglomerates made up of many primary particles, represented as an Average Agglomeration Number significantly greater than 10. After removal of the oversized agglomerates through settling and filtration, only an unacceptably small percentage of material remained in the dispersed state (often with a 90% loss).

### 3 Rocket-Grade Kerosene RP-1

It was always assumed that the abbreviation RP stands for **R**ocket **P**ropellant, but other interpretations are **R**efined **P**etroleum-1 (RP-1).

#### 3.1 Production of RP-1

RP-1 is produced by refining crude petroleum feed stocks, in particular hydrotreating by reduction with hydrogen over catalysts. That treatment reduces the sulfur and aromatics content and totally eliminates any olefin content.

As of 2004, there was one vendor for RP-1 in the US, Haltermann Products of Channelview, TX (near Houston, now a division of Monument Chemicals, Inc.), which has been the sole vendor of RP-1 for at least 16 years. Production has been around 300000 gallons/year. It appears that even if the requirements for RP-1 should increase by a factor of 100, sufficient capability for producing this fuel is available in the USA.

In the years leading up to the selection of RP-2, three different grades of RP-1 were specified with an eye toward decreasing the sulfur concentration specification limits: TS-30 (**T**otal **S**ulfur less than 30 ppm, mass/mass, which was similar to typical as-delivered RP-1), TS-5 (**T**otal **S**ulfur less than 5 ppm, mass/mass), and UL RP-1 (**U**ltra**L**ow sulfur, less than 100 ppb, mass/mass). Experience showed that ultralow sulfur RP-1 showed significant performance benefits over TS-5 with only marginally greater costs; thus, this fluid (ultralow) was eventually selected to become “RP-2” (and the RP-1 sulfur limit was lowered from 500 to 30 ppm, mass/mass). Thus, RP-1 and RP-2 have emerged as the primary kerosene rocket propellants for use in US rocket motors. It is noted that the specification for RP-1 and RP-2 allowable aromatic content are the same; however, a lower aromatic content is commonly found in RP-2. Other specifi-

cation limits, including those related to the distillation behavior, viscosity, density, freezing point, and net heat of combustion, are identical for RP-1 and RP-2.

### 3.2 Physical Properties of RP-1

Physical properties of RP-1 and RP-2 were measured and are now available on-line in the NIST Reference Fluid Thermodynamic and Transport Properties (RefProp) computer program [157, 158]. The free NIST mini-REFPROP, which can be downloaded from the web [159], does not contain RP-1 or RP-2 but contains *n*-dodecane as an example. The properties of *n*-dodecane are very similar to those of RP-1 and RP-2 and *n*-dodecane is a constituent of both RP-1 and RP-2.

Because the physical properties of RP-1 and RP-2 can vary over a wide range (within the range specified by MIL-SPEC), surrogate mixtures prepared from known amounts of pure hydrocarbons are sometimes used to calibrate instruments or to standardize analytical methods (see Section 3.3.3).

The density and viscosity, the thermal conductivity of liquid and solid RP-1, the linear coefficient of thermal expansion, the specific heat, and cubical coefficient of thermal expansion of liquid and solid RP-1 were determined [160]. These data are included in Table 16.

The density, velocity of sound, and viscosity of two RP-1 and RP-2 samples were measured with three different instruments [163, 164]. Data at ambient atmospheric pressure were obtained with a rapid characterization instrument from 278 to 343 K that measured both the velocity of sound and density of the liquids. In parallel, adiabatic compressibilities were derived from that data. Densities of the compressed liquids were measured in an automated apparatus from 270 to 470 K and at pressures up to 40 MPa. Viscosities of the two liquids were measured in an open gravitational capillary viscometer at ambient atmospheric pressure from 293 to 373 K. Correlations have been developed to express the measured properties within the estimated uncertainties of the experimental data and to allow extrapolations beyond the range of the measurements. The designation RP-1 has been around for a very long time, but the property requirements of the fuel it describes have changed over time [165]. A melting (freezing) point of a sample of RP-1 was reported to be 224 K (−56 °F), but the MIL SPEC required freezing temperature is 222 K maximum (−60 °F maximum) [85].

#### 3.2.1 Density of RP-1

One of the oldest density determinations of RP-1 found a density of  $0.7987 \pm 0.0005 \text{ g/cm}^3$  at 298 K (25 °C) [160]. The density as a function of temperature within the range 228 to 298 K (−45 to +25 °C) can be calculated from the equation:

$$\rho = 0.7987 - 0.0036(t - 25.0)$$

where  $\rho$  is the density in  $\text{g/cm}^3$  and  $t$  is the temperature in °C.

**Table 16:** Physical properties of RP-1.

| Property                                                              | SI units                                        | Other units                                                                                               | References |
|-----------------------------------------------------------------------|-------------------------------------------------|-----------------------------------------------------------------------------------------------------------|------------|
| Freezing point                                                        | 224 K                                           | −56 °F                                                                                                    | [85]       |
|                                                                       | < 222 K                                         | < −60 °F                                                                                                  | [80]       |

**Figure 1:** Density of RP-1. (Reproduced and modified from [166].)

The density of RP-1 was determined by the Archimedes method with an aluminum sinker between 274 and 316 K [166] (Figure 1). The density can be calculated from the equation:

$$\rho = 815.2 - 0.6778t - 5.316 \times 10^{-4}t^2$$

where  $\rho$  is the density in kg/m<sup>3</sup> and  $t$  is the temperature in °C.

The density of RP-1 has been measured with a density and sound speed analyzer DSA 5000, Anton-Paar Corporation from 278 to 343 K at ambient (0.083 MPa) pressure and compressed liquid density measurements were made with a fully automated densimeter for elevated pressures between 0.083 and 40 MPa [163, 164]. The density of RP-1 as a function of temperature and pressure is illustrated in Figure 2. In Figure 2, the highest pressurized data point was taken at 40 MPa and the lowest data point was taken at 0.5 MPa.

The density of RP-1 at atmospheric pressure can be calculated from the equation:

$$\rho = 287.67129 \times 0.53365016^{-\left[1 + \left(\frac{1-T}{574.26284}\right)^{0.6288664}\right]}$$

where  $\rho$  is the density in kg/m<sup>3</sup> and  $T$  is the temperature in kelvin.

The density of RP-1 has been measured with a constant-volume piezometer immersed in a precision liquid thermostat within the temperature range 301 to 745 K and at pressures up to 60 MPa [167]. The uncertainty of density, pressure, and tempera-

ture measurements were estimated to be 0.1%, 0.05%, and 15 mK respectively. The measured values of density were compared with data reported in the literature and with values calculated from a surrogate mixture model (via the equation of state). The average absolute deviation (AAD) between the presented data and the values reported in the literature was only 0.13% (Figure 3; Table 17). In addition to density as a function

of temperature at ambient atmospheric pressure, densities were measured at elevated temperatures and elevated pressures under conditions similar to those encountered in the cooling channels of bipropellant rocket engines (Figures 4 and 5; Table 18).

The density of eleven synthetic samples of RP-1 was measured using a commercial density and sound speed analyzer, the DSA 5000 from Anton Paar, which could simultaneously measure these two properties over the temperature range 278 to 343 K [161] (Figure 6). The variability observed in density over the 11 RP-1 samples was relatively constant as a function of temperature, ranging from 1.3% at 278 K to 1.4% at 343 K. The average density is shown as a red solid line.

### 3.2.2 Velocity of Sound and Compressibility of RP-1

The velocity of sound in RP-1 and RP-2 was measured with a density and sound speed analyzer DSA 5000, Anton-Paar Corporation, at ambient (0.083 MPa) pressure [163]. The velocity of sound of RP-1 and RP-2 as a function of temperature is illustrated in Figure 7.

Adiabatic compressibilities in liquids can be calculated from sonic velocity data with the aid of the following equation:

$$\beta_a = \frac{1}{\rho c^2}$$

where  $\beta_a$  is the adiabatic compressibility in  $\text{m}^2/\text{N}$ ,  $\rho$  is the density in  $\text{g}/\text{m}^3$ , and  $c$  is the velocity of sound in  $\text{m}/\text{s}$ . The adiabatic compressibility of RP-1 and RP-2 is illustrated in Figure 8.

**Figure 7:** Velocity of sound of RP-1 and RP-2 as a function of temperature. (Reproduced and modified from [163].)

The temperature dependence of the velocity of sound of RP-1 can be expressed by the polynomial equation:

$$v = 2797.7044 - 6.1546685 T + 3.8195817 \times 10^{-3} T^2$$

where  $v$  is the velocity of sound in m/s and  $T$  is the temperature in kelvin.

In a similar series of tests, the velocity of sound of 11 synthetic samples of RP-1 was again measured using a commercial density and sound speed analyzer, the DSA 5000 from Anton Paar, which could simultaneously measure these two properties over the temperature range from 278 to 343 K [161] (Figure 9). The variability observed in sound speed over the 11 RP-1 samples was relatively constant as a function of temperature, ranging from 0.6% at 278 K to 0.8% at 343 K. The average velocity of sound is shown as a red solid line.

**Figure 8:** Adiabatic compressibility of RP-1 and RP-2. (Reproduced and modified from [163].)

Based on the velocity of sound data shown in Figure 9, the adiabatic compressibility of RP-1 was calculated using known equations. The adiabatic compressibility of RP-1 as a function of temperature is shown in Figure 10. The average compressibility is shown as a red solid line. Single-point adiabatic compressibility of RP-1 was listed as  $6.41 \times 10^{-7} \text{ kPa}^{-1}$  at 294 K and single-point isothermal compressibility of RP-1 was listed as  $5.8 \times 10^{-7} \text{ kPa}^{-1}$  at 283 K.

Generally, as a first approximation, it has been assumed that kerosenes with the same density and viscosity all have the same compressibility and coefficients of thermal expansion. This assumption has been applied to RP-1 [25]. Figure 11 shows the isothermal compressibility of RP-1 as a function of temperature. The auxiliary variable is Jessup's volume modulus. Numerical data for isothermal compressibility of RP-1 are listed in Table 19. These are the same numbers that Figure 11 is based on. The numbers

**Figure 9:** Velocity of sound in RP-1 as a function of temperature. (Reproduced and modified from [161].)

next to the curves in Figure 11 are the numbers in the first column of Table 19. Jessup's volume modulus is defined as:

$$J = \frac{1}{d \sqrt{\log(1000 \times S)}}$$

where  $d$  is the density at 289 K (60 °F) and  $S$  is the kinematic viscosity at 311 K (100 °F).

### 3.2.3 Vapor Pressure of RP-1

The vapor pressure of RP-1 varies widely, depending on the source of the propellant. Even samples that meet the fractionated distillation curve requirements of the MIL-SPEC may differ from one sample to another when measuring the vapor pressure as a function of temperature. When developing surrogate fuels, the formulators have tried to match the vapor pressure curves of RP-1 and the surrogate, but that is not always a close match. There are surprisingly few data on vapor pressure of RP-1 (or

RP-2) in the literature. If no other data are available, the vapor pressure of *n*-dodecane can be used as a surrogate fluid. The vapor pressure of RP-1 as a function of temperature has been measured before and after trace volatiles were removed (Figure 12). The center curve showing the average vapor pressure after trace volatiles are removed is generally used for calculations.

### 3.2.4 Viscosity of RP-1

The viscosity of RP-1 was measured by an open gravitational capillary Ubbelohde viscometer by a method described in ASTM method D 445-03 [166]. The kinematic viscosity of RP-1 as a function of temperature is shown in Figure 13.

Figure 12: Vapor pressure of RP-1 before and after removing trace volatiles.

Figure 13: Kinematic viscosity of RP-1 as a function of temperature. (Reproduced and modified from [166].)

The viscosity of two RP-1 and RP-2 samples have been measured in an open gravitational capillary viscometer at ambient atmospheric pressure from 293 to 373 K [163, 164] (Table 20 and Figure 14). Correlations have been developed to express the measured properties within the estimated uncertainties of the experimental data and to allow extrapolations beyond the range of the measurements.

**Table 20:** Viscosity of RP-1

| Temperature $T$ | Kinematic viscosity $\nu$<br>$\text{mm}^2 \text{s}^{-1}$ | Dynamic viscosity $\eta$<br>$\text{mPa s}$ |
|-----------------|----------------------------------------------------------|--------------------------------------------|

Data source: [163,164]

**Figure 14:** Kinematic viscosity of RP-1 and RP-2 as a function of temperature. (Modified from [163, 164].)

The viscosity of RP-1 has been measured with a capillary flow technique at high temperatures and high pressures [168]. Measurements were made at seven isobars (0.101, 10, 20, 30, 40, 50, and 60 MPa) over the temperature range 301 to 744 K, up to thermal decomposition temperature. The combined expanded uncertainty of the viscosity, pressure, and temperature measurements at 0.95 confidence level with a coverage factor of  $k=2$  was estimated to be 2%, 0.05%, and 0.02 K respectively. The reliability and accuracy of the experimental method and correct operation of the experimental apparatus were confirmed with comparison measurements on pure toluene for two selected isotherms of 583.15 and 603.15 K at pressures between 10 and 40 MPa. The experimental and calculated values for the viscosity of pure toluene from NIST/REFPROP showed excellent agreement within their experimental uncertainty. The measured values of viscosity for RP-1 were compared with the values predicted from a surrogate mixture model (NIST/REFPROP). The significant effect of thermal decomposition (thermal stress) on the measured values of viscosity of RP-1 at high temperatures (above 650 K) limited the upper temperature up to which measurements could be extended. As Figure 15 shows, at constant temperatures the viscosity of RP-1 increases almost linearly with increasing pressure. Also, Figure 15 demonstrates that the experimental rate of pressure changes  $(\partial\eta/\partial P)_T$  along the various isotherms (dotted lines) is considerably different from the predictive behavior of  $\eta$ - $P$  isotherms (solid lines), especially at low temperatures. The measured values of the viscosity of

**Figure 15:** Isotherms of dynamic viscosity of RP-1 as a function of pressure. (Reprinted and modified from [168], with permission from ©2019 Elsevier; permission conveyed through RightsLink.)

RP-1 can be best represented by fitting  $\ln \eta$  to a linear Arrhenius correlation model, which is consistent with the theory of rate processes.

Comparing viscosity of RP-1 according to Abdulagatov and Akhmedova-Azizova [168] with viscosity data for RP-2 reported by Laesecke and Cousins [169], it appears that at all pressures RP-2 has a higher viscosity than RP-1.

The viscosity and density of 11 synthetic samples of RP-1 were measured using a commercial viscodensimeter, the SVM 3000 from Anton Paar, which can simultaneously measure viscosity and density over the temperature range 263 to 373 K and at ambient pressure. Density was measured with a vibrating-tube densimeter made of borosilicate glass. Viscosity was measured with a Stabinger rotating concentric cylinder viscometer [161] (Figure 16). The variability observed in dynamic viscosity over the 11 RP-1 samples was significantly larger than that observed for either density or velocity of sound and, unlike the previous properties, it changed considerably with temperature. The overall variability for the 11 samples ranged from 14.1% at 263 K to

**Figure 16:** Dynamic viscosity of RP-1 as a function of temperature. (Reproduced and modified from [161].)

6.2% at 373 K. The mean dynamic viscosity is shown as a solid red line. A similar graph is available for kinematic viscosity on the same samples.

Single-point kinematic viscosity data for RP-1 were reported as  $3.02 \times 10^{-6} \text{ m}^2/\text{s}$  ( $3.02 \text{ cSt}$ ) at 274 K and  $2.17 \times 10^{-6} \text{ m}^2/\text{s}$  ( $2.17 \text{ cSt}$ ) at 323 K [85]. Historical data for absolute viscosity of RP-1 are displayed in Figure 17.

Figure 17: Historical data for absolute viscosity of RP-1.

### 3.2.5 Thermal Conductivity of RP-1

The thermal conductivity of RP-1 was measured with a hot wire method at pressures up to 70 MPa [85]. Measurements were made at increasing temperatures on the original sample from 300 to 600 K. At the end of the experiments, in particular those at higher temperatures, the hot wires were encrusted with coke deposits, which hindered further measurements. The thermal conductivity of RP-1 at very high pressures is illustrated in Figure 18, which shows the sample density instead of pressure on the abscissa axis of the graph. Thermal conductivity increased with increasing pressure and with temperature. Density decreased with increasing temperature.

The thermal conductivity of liquid RP-1 was measured by a coaxial-cylinder (steady-state) technique. With this method, the heat generated in an inner emitting cylinder is conducted radially outward through the narrow, fluid-filled annulus to a coaxial receiving cylinder [170]. The gap between cylinders (thickness of the liquid annulus) was  $d = 0.97 \times 10^{-3} \text{ m}$ . The measured values of thermal conductivity of RP-1 agreed well (within 1.0%) with the reported literature data and the values calculated with a reference correlation equation for a surrogate hydrocarbon mixture. The RP-1

**Figure 18:** Thermal conductivity of RP-1 at very high temperatures and pressures. (Reproduced and modified from [166].)

**Figure 19:** Thermal conductivity of RP-1 as a function of temperature for two different pressures, 0.1 and 6 MPa. (Reprinted and adapted from [170], with permission from ©2009 American Chemical Society; permission conveyed through RightsLink.)

sample measured in this work came from the same batch as that used by Magee et al. [166]. The thermal conductivity of RP-1 as a function of temperature is shown in Figure 19 for two different pressures, 0.1 and 6 MPa. The data points marked with three different symbols are from three consecutive runs with fresh samples. The solid line is what is expected for a surrogate model from Magee et al. [166] and the dashed lines are what is expected for a surrogate model from Huber et al. [19]. The two curves are very similar, except that one is for sea-level atmospheric pressure and the other is for high pressure (6 MPa). Figure 20 shows the thermal conductivity of RP-1 as a function of pressure for four isotherms.

**Figure 20:** Thermal conductivity of RP-1 as a function of pressure for four isotherms. (Reprinted and adapted from [170], with permission from ©2009 American Chemical Society; permission conveyed through RightsLink.)

### 3.2.6 Heat Transfer Coefficient of RP-1

A series of tests to measure the heat transfer in RP-1 and to examine coking problems were performed in a NASA Heated Tube Test Facility [171]. The facility simulates regenerative cooling by flowing room-temperature RP-1 through resistively heated copper tubing. A regression analysis was performed on the data to determine the heat transfer correlation for the Nusselt number as a function of Reynolds and Prandtl numbers. Each measurement and calculation was analyzed to identify sources of uncertainty, including RP-1 property variations. Density, enthalpy, thermal conductivity, and viscosity data for RP-1 fuel were used to calculate several parameters, including the Re and Pr numbers used in the heat transfer correlation. Although RP-1 has been used extensively in the rocket industry, these properties have not been closely studied at tem-

peratures and pressures above standard conditions. Data from a prediction model, which relates properties to a known reduced state based on the principal of corresponding states, was used to determine fluid properties in the data reduction. Similar models and limited data are available for comparison, but the data are quite different from each other. The temperature at the inner wall of the tube was calculated by modeling the resistivity of the tube, the energy input, and the outer wall temperature. The difference between the inner and outer wall temperatures is about 5.5 K (10 °F). The uncertainty in the inner wall temperature from modeling assumptions in this calculation was estimated as  $\pm 1.1$  K ( $\pm 2$  °F). The enthalpy at the inlet of the tube was determined from the fluid temperature and the property data. Downstream from this point, the enthalpy was calculated at the location of each thermocouple by modeling the energy input over each section of the tube. The mean fluid temperature at each location was then determined from the enthalpy using the property data. Assuming a reasonably good model, the uncertainty of this calculation was estimated to be about 3%. It was shown that the overall systematic uncertainty in a predicted Nu number can be as high as 35%. The random uncertainty in the heat transfer correlation is significant and can be as high as 12%. The overall uncertainty in Nu number is the RSS of the random and systematic components and could be as high as 36%. This has a significant impact on engine design parameters. Additional (somewhat outdated) information on heat transfer to RP-1 is published in Greenfield [172], Hines [173], and Seader and Wagner [174].

While studying the heat transfer to RP-1 or diethylcyclohexane under supercritical conditions and with very high wall temperatures, the investigators noticed audible pressure oscillations within the frequency range from 1 to 10 kHz, which led to improved heat transfer, but also caused severe cavitation erosion damage of the surface of the metal tubes [175]. The amplitude of the oscillations was  $\pm 1.4$  MPa ( $\pm 14$  atm). It is suspected that such oscillations in the cooling jackets can couple with combustion oscillations in the combustion chamber and lead to undesirable or even dangerous overall combustion instabilities. The heat-transfer oscillations started only after the heat transfer exceeded a certain reproducible threshold. If the inlet temperature of RP-1 is 339 K (66 °C), the pressure is 4.83 MPa (47.7 atm), the flow velocity 11.9 m/s, and the temperature difference  $T_{\text{wall}} - T_{\text{fluid}} = 278$  K (278 °C); the nominal heat transfer is  $326 \text{ W cm}^{-2}$  ( $= 78 \text{ cal cm}^{-2} \text{ s}^{-1}$ ). Once the temperature difference  $T_{\text{wall}} - T_{\text{fluid}}$  exceeds 340 K (340 °C), heat transfer increases steeply and oscillations can occur. The vibration produced audible noise, increased heat transfer, and resulted in tube splits and pinhole leaks. Similar observations were made with other hydrocarbons [33] and liquid hydrogen.

### 3.2.7 Thermodynamic Properties of RP-1

#### 3.2.7.1 Heat Capacity of RP-1

Heat capacities at constant pressure were measured with a flow calorimeter that operates at conditions up to 671 K and 60 MPa. The isobaric heat capacity of RP-1 has been measured with a vacuum adiabatic calorimeter immersed in a precision liquid thermostat within the temperature range 293 to 671 K and at pressures up to 60 MPa [176]. The uncertainty of heat capacity, pressure, and temperature measurements were estimated to be 2–2.5%, 0.05%, and 15 mK respectively. The measured values of heat capacity were compared with the values calculated from a surrogate mixture model (EOS). The AAD between these data and the values calculated with an EOS was 0.81%. Table 21 gives the measured heat capacity for a wide range of temperatures and pressures. The heat capacity as a function of temperature is an almost linear function, with deviations at the upper end of the temperature range, as illustrated in Figure 21 for two different pressures, 20 and 40 MPa.

**Table 21:** Experimental isobaric heat capacities of RP-1.

| <i>T</i> , K | Isobaric heat capacity, <i>c<sub>p</sub></i> , kJ kg <sup>−1</sup> K <sup>−1</sup> |                    |        |        |        |        |        |

#### 3.2.7.2 Enthalpy of Formation of RP-1

The NASA CEC program assumes a formula of C<sub>1</sub>H<sub>1.95</sub> and an enthalpy of formation of −24717.7 kJ/kg mol for RP-1 [162]. The US Navy PEP Program offered two very different sets of data for RP-1 [37] (Table 22).

The different heats of formation when reported in units of kJ/mol are often based on different assumptions for the average molecular mass of RP-1. One avoids this variability by working only with the mass-specific enthalpy of formation, which still varies between −2540 kJ/kg (−60.6 kcal/100 g), assuming C<sub>7.060190</sub>H<sub>14.97479</sub>, and −1760 kJ/kg (−42.0 kcal/100 g) assuming CH<sub>1.9063</sub>, depending on which source one can trust.

**Table 22:** Enthalpy of formation of RP-1.

| Compound   | Formula                           | Enthalpy of formation |       |
|------------|-----------------------------------|-----------------------|-------|
|            |                                   | kJ/kg                 | cal/g |
| RP-1       | C <sub>1</sub> H <sub>2</sub>     | −5607                 | −1340 |
| RP-1 (RPL) | C <sub>100</sub> H <sub>195</sub> | −1510                 | −361  |

### 3.2.7.3 Enthalpy of Evaporation of RP-1

Assuming that the gross formula of RP-1 is  $C_{12}H_{23.4}$ , the enthalpy of evaporation of RP-1 was predicted to be 308 kJ/kg based on NMR and GC measurements [38]. Other sources reported heats of vaporization between 246 and 291 kJ/kg.

### 3.2.7.4 Heat of Combustion of RP-1

The upper heat of combustion of RP-1 (gross) is 46309 kJ/kg at 298 K (19923 BTU/lb). The lower heat of combustion of RP-1 is (net) 43328 kJ/kg (18640 BTU/lb) [85]. A chemical GC-MS analysis of a specific sample of RP-1 was followed by determination of the heat of combustion in a calorimeter [166].

### 3.2.8 Optical Properties of RP-1

Knowledge of the refractive indices of rocket propellants is of great importance in many engineering and scientific applications. For example, optical constants are needed to calculate the focusing of a laser beam used to ignite rocket fuels inside an engine. These optical parameters are not directly measurable, but can be derived from measured quantities such as the transmission and reflection coefficients.

Complex index-of-refraction values of RP-1 were measured at several different laser wavelengths of 0.193  $\mu\text{m}$  (ArF excimer), 0.4765  $\mu\text{m}$  (argon ion), 0.488  $\mu\text{m}$  (argon ion), 0.5145  $\mu\text{m}$  (argon ion), 0.532  $\mu\text{m}$  (Nd-YAG, frequency doubled), 0.6328  $\mu\text{m}$  (He-Ne), 1.064  $\mu\text{m}$  (Nd-YAG), and 10.5915  $\mu\text{m}$  ( $\text{CO}_2$ ), and the imaginary part of the index of refraction ( $k$ ) was determined by traditional transmission methods [177]. The refractive index of RP-1 varied between 1.44 and 1.50 within the wavelength range 0.1–10  $\mu\text{m}$ .

### 3.2.9 Critical Point Properties of RP-1

The critical temperature of RP-1 was listed as 676 to 689 K, with a critical pressure of 2140 to 2170 kPa.

## 3.3 Chemical Properties of RP-1

### 3.3.1 Contaminant Levels in RP-1

Over the course of several decades, the tolerable sulfur concentration in kerosene for rocket engine use has been lowered from 500 to 30 ppm to 1 ppm and may eventually end up within the ppb range.

### 3.3.2 Chemical Composition of RP-1

A GC-MS analysis of RP-1 revealed at least 24 major constituents (peak area counts in excess of 1%) ranging from  $C_{11}$  fluids such as 2,6-dimethylnonane to  $C_{14}$  fluids such as

2-methyltridecane that represented about 40% of the total area counts [178, 179]. Overall, the sample showed approximately 350 peaks that could be easily distinguished from noise level and perhaps twice that number that were slightly above noise level. The predominant species were linear and branched paraffins, and one- and two-ring cyclic paraffins of 11–14 carbon atoms. Aromatics and olefins were not found in this sample, but aromatics and olefins were reported by other investigators.

A long-established hydrocarbon fuel, RP-1 continues to be widely used as the kerosene component in some rocket propulsion systems. The desire in recent years to re-use rocket engines many times, rather than a single time, has led to reformulations of RP-1 and to the formulation of RP-2. In terms of processing, increased hydro-treating of the component feedstock fluids used in the manufacture of RP-1 can lower the sulfur, olefin, and aromatic content significantly. The resulting fuels have demonstrably lower metal corrosion effects and are thus more amenable to multiple use rocket engines. The reformulated RP-1 mixtures have been extensively studied in terms of thermophysical properties, combustion processes, and kinetics and performance. Still unknown is how compositional variability resulting from the various blending strategies affects both the properties and the ability to correctly predict the fluid behavior with mathematical models. In trying to develop a predictive procedure, 11 batches of RP-1 were prepared to represent the range of formulation recipes [180–182]. The density, velocity of sound, and viscosity of these same 11 samples were later measured and reported [161]. These results were already shown here in individual property sections for RP-1 (see Section 3.2). For each of these representative formulations, the compositional variability was tested with the ADC method. This method is an improvement of classical distillation curve techniques. It features: **(1)** a composition explicit data channel for each distillate fraction (for both qualitative and quantitative analysis); **(2)** temperature measurements that are true thermodynamic state points that can be modeled with an EOS; **(3)** temperature, volume, and pressure measurements of low uncertainty suitable for EOS development; **(4)** consistency with a century of historical data; **(5)** an assessment of the energy content of each distillate fraction; **(6)** trace chemical analysis of each distillate fraction; and **(7)** corrosivity assessment of each distillate fraction. All applicable data channels of the ADC method were used to show the compositional variability of RP-1 and to show how the variability impacts predictive modeling. It was concluded that the variabilities of RP-1 and RP-2 were significant and perhaps higher than expected.

During the past decade several important improvements were introduced into the measurement of distillation curves for complex fluids. One method was a significant improvement over previous approaches, featuring a composition-explicit data channel for each distillate fraction (for both qualitative and quantitative analysis) and an assessment of the energy content of each distillate fraction, among other features [183]. One modification was achieved with a new sampling approach that allowed precise qualitative as well as quantitative analyses of each fraction, on the fly. This method was applied to the measurement of a wide variety of fluids, including hydro-

carbons, gasoline, jet fuel, diesel fuels (both petroleum-derived and biodiesel), crude oils, RP-1, RP-2, and TS-5. Not only the distillation curves but also the composition-explicit information was used to characterize distillate cuts in terms of composition and available energy content. The measure used for the fluid energy content was the composite enthalpy of combustion for each component selected for identification in each distillate fraction. Overall, the distillation curves and enthalpy data for RP-1, RP-2, and TS-5 were remarkably similar.

Although the range of compositional variability observed for JP-8 is not expected for RP-1, manufacturing process changes and fluctuating feedstock availability can cause subtle compositional variation, which may cause concern for some applications. Whether or not these changes are consequential from an engine or vehicle standpoint depends on the system. Maintaining fuel integrity is universally important for launch applications as vehicle and payload development time and cost are invaluable, especially for manned missions. For the development of new engines, re-examination of the variability in fuel composition, and especially its impact on properties and performance, must be done periodically and repeatedly. Table 23 summarizes literature references for RP-1 hydrocarbon class composition [184].

**Table 23:** Reported RP-1 hydrocarbon class composition.

| Hydrocarbon type<br>Composition    | References     |        |                  |        |                  |

Data source: [184]

The composition of seven synthetic fuel mixtures representing a wide range of RP-1 properties was compared with the results of GC-MS-IR analysis of real samples of RP-1 [161].

### 3.3.3 Surrogate Mixtures Representing RP-1

Because the composition of commercial samples of RP-1 may vary widely depending on source and processing techniques, surrogate mixture recipes (“models”) have been developed that can be used to reproducibly reconstitute a mixture of hydrocarbons in the laboratory, starting with known amounts of pure hydrocarbons as ingredients. Whereas real-world RP-1 may contain up to several hundred constituents, surrogate mixtures would normally contain no more than 20 ingredients. Such surrogate mixtures can then be used to calibrate instruments, and to compare analytical methods, for instance, in a nation-wide round-robin analysis effort. Although surrogate mixtures are often formulated on the basis of the ability of a particular mixture to reproduce a particular property, there is usually a desire to employ surrogate mixtures that are physico-chemically authentic. This means that, provided that the primary purpose is satisfied, researchers are inclined to choose mixtures that have physical and chemical properties appropriate to the finished fuel. Such mixtures have been synthesized for RP-1 and several other kerosene types [186].

Other proposed recipes for surrogate mixtures for RP-1 were published [185]. The first step in developing surrogate fluid mixture for RP-1 was a thorough chemical analysis by GC-MS of a specific RP-1 fuel sample provided by the Fuels Branch of the Air Force Research Lab, Wright-Patterson AFB, OH, which gave 37 constituent fluids [166]. A detailed analysis shortened this list to 20 potential constituent fluids for a surrogate mixture. The lightest component identified was neohexane, and the heaviest was hexadecane. The list included linear and branched alkanes, mono and bicyclic paraffins, aromatics, and linear and branched olefins. The final mixture contained 14 constituent fluids, and represented the density to within 0.3%, the heat capacity to within 7%, the thermal conductivity to within 3%, the viscosity to within 3% at atmospheric pressures, and 10% at 60 MPa, and the boiling point at local atmospheric pressure to 0.5%. It had an overall molar mass of 164.6, a H/C ratio of 1.95, and an approximate chemical formula of  $C_{11.8}H_{23.0}$ . The overall composition was (by mol-%) 27.4% alkanes, 26.6% alkenes, 18.5% monocyclic paraffins, 22.4% bicyclic paraffins, and 5.1% aromatics. This mixture was intended as a surrogate; it did not have the actual mixture composition, but rather a mixture that approximated the behavior of a particular RP-1 sample that was investigated.

Surrogate hydrocarbon fuel mixture models were developed to represent the thermophysical properties of two kerosene rocket propellants, RP-1 and RP-2 [19]. The surrogates were developed with a procedure that incorporated experimental data for the density, sound speed, viscosity, thermal conductivity, and the ADCs for samples of the two fuels. The surrogate for RP-1 contained four components (numbers in mo-

lar fractions) 0.354  $\alpha$ -methyldecalin, 0.150 5-methylnonane, 0.183 *n*-dodecane, and 0.313 heptylcyclohexane. Comparisons with experimental data demonstrated that the models were able to represent the density, sound speed, viscosity, and thermal conductivity of both fuels to within (at a 95% confidence level) 0.4, 2, 2, and 4% respectively. The volatility behavior, as measured by the ADCs, is reproduced to within 0.5%.

In continuation of this work, two different surrogate mixtures for RP-1 were formulated, one containing olefins and aromatics, the other not containing any of these [187]. Experimental and calculated thermophysical properties of two samples of RP-1 obtained from different batches of RP-1 that exhibit compositional variations were compared. One sample was atypical, owing to a high olefin content. The greatest effects of this significant compositional variability were seen in the viscosity and the distillation curve. The effects of compositional variations were shown for several thermophysical properties including density, sound speed, viscosity, thermal conductivity, and volatility (as expressed by the distillation curve).

Compositional variability of aerospace kerosene formulations influence performance or the design of practical combustion devices, particularly as relatively extreme operating conditions can result in increased sensitivity to small variations in composition-related physical properties. Twelve laboratory-scale RP-1 fossil-fuel-derived surrogate formulations were prepared that met specification requirements but were blended from nine chemically unique feedstocks, thereby representing the expected compositional variation for currently produced fuel [184]. Chemical composition was characterized in terms of hydrocarbon types and was compared between the various formulations. Composition explicit distillation curve, density, viscosity, heat of combustion, and hydrogen content were determined for each of the 12 blends and several other RP-1 samples carried along for comparison.

#### 3.3.4 Specifications for RP-1

Military specifications for RP-1 have undergone many changes during the past decades. The first release of the RP-1 specification (MIL-F-25576A) was issued on 3 January 1957. The specification restricted levels of olefins (<1.0% by weight), aromatics (<5.0 by weight), and dissolved sulfur (<0.05% by weight), and alleviated most of the performance degradation problem due to soot, coking, and gum deposits. Combined with other specifications regarding hydrocarbon constituents, density range, and heat of combustion, it also ensured repeatable propulsion performance within acceptable limits. In Table 24, an attempt is made to give a chronological list of MIL SPECS for RP-1 that may have been in effect at one time or another.

**Table 24:** Military specifications for rocket-grade kerosene RP-1 and RP-2.

| Designation               | Pages | Date issued   | Changes made                     |
|---------------------------|-------|---------------|----------------------------------|
| MIL-P-25576               | —     | —             | —                                |
| MIL-P-25576A              | —     | —             | —                                |
| MIL-P-25576B              | —     | January 1959  | —                                |
| MIL-P-25576C              | 8     | February 1967 | —                                |
| MIL-P-25576C Amendment 1  | 1     | November 1967 | —                                |
| MIL-P-25576C Amendment 2  | 1     | June 1982     | Olefins limit raised to 2 vol.-% |
| MIL-DTL-25576D            | 12    | May 2005      | Addition of RP-2 as a new grade  |
| MIL-DTL-25576E            | 11    | April 2006    | Dye addition mandatory for RP-1  |
| MIL-DTL-25576E (Notice 1) | 1     | January 2011  | —                                |

Starting with MIL-DTL-25576D, this specification now covers two grades of rocket propellant kerosene for use in rocket engines:

RP-1 Normal production, total sulfur content of 30 mg/kg (maximum), suitable for most uses;

RP-2 Processed RP-1, total sulfur content of 100 µg/kg (maximum).

The specification requirements of RP-1 and RP-2 are listed in Table 25 [80].

In looking at the requirements for RP-1 and RP-2, the sulfur content has been limited because sulfur corrodes copper-containing engine components and may affect the thermal stability of kerosenes [188]. In particular, the main difference between RP-1 and RP-2 is the lower sulfur content in RP-2 that has been reduced by hydrogenation treatment. The desulfurization treatment is also called “sweetening,” which is a process to remove the sour (acidic, sulfur-bearing) contaminants in petroleum products. Sulfur that is contained in mercaptans and thiophenes is more difficult to remove.

The aromatics content has been limited because aromatics (xylene, tetralin) and olefins contain less hydrogen and result in higher average molecular mass of the exhaust products in a rocket engine. For the same reason, the hydrogen content has been specified to be a minimum of 13.8 mass-%. For comparison, a hydrocarbon with the gross formula  $\text{CH}_2$ , the simplified gross formula for hydrocarbons, contains 14.37 mass-% hydrogen. Olefins have been limited because they may autoxidize during storage and form resins that may clog filter screens and injector orifices.

The flash point for both grades of RP has been limited to above 333 K (140 °F) because a higher content of combustible volatiles with lower flash points would change the stoichiometry (shift it to fuel-rich) in the vapor phase at ignition when kerosene is first injected into a rocket engine, and because a fuel-rich mixture is more difficult to ignite.

**Table 25:** Specification requirements of RP-1 and RP-2 per MIL-DTL-25576E.

| Property                                                    | Limits            |               | ASTM Test method    |
|-------------------------------------------------------------|-------------------|---------------|---------------------|
|                                                             | RP-1              | RP-2          | D 86                |

### 3.4 Analysis of RP-1

Eighty-seven [189] different hydrocarbons have been identified in RP-1, the fractions of which could change from one batch to another.

### 3.4.1 Copper Strip Corrosion

Copper strip corrosion is a semi-technical subjective test that appears to have little relevance in an advanced fuel specification. It was developed in the 1940s to ensure that the fuels are not too acidic. The test involves soaking a polished copper coupon in the test fuel for 2 h at 212°F, after which the specimen is evaluated against a standard. It is not sure whether any fuel sample has ever failed this test, even fuels with over 500 ppm sulfur.

### 3.4.2 Gas Chromatography

Ongoing efforts in predicting fuel chemical and physical behavior through modeling put greater emphasis on attaining detailed and accurate actual fuel properties and fuel composition information. Traditionally, one-dimensional GC combined with MS has been employed to provide chemical composition information. Building on approaches that make use of GC-MS, comprehensive two-dimensional (2D) gas chromatography combined with time-of-flight mass spectrometry (GC  $\times$  GC-TOFMS) using a reversed column format RTX-wax column for the first dimension, and an RTX-1 column for the second dimension provides substantially more chemical composition information about these complex fuels [190]. By applying chemometric data analysis, specifically partial least-squares (PLS) regression analysis, it was possible to readily model (and correlate) the chemical compositional information provided by the use of GC  $\times$  GC-TOFMS to RP-1 fuel property information such as density, kinematic viscosity, net heat of combustion, hydrogen content, etc. This method readily identified compounds that contribute significantly to measured differences in fuel properties based on results from the PLS models.

The GC  $\times$  GC-TOFMS data were analyzed using PLS regression chemometric analysis to model and predict ADC data for ten RP-1 fuels that were previously analyzed using the ADC method [191]. The PLS modeling provided insight into the chemical species that impact the ADC data. The PLS modeling correlated compositional information found in the GC  $\times$  GC-TOFMS chromatograms of each RP-1 fuel, and their respective ADC, and allowed prediction of the ADC for each RP-1 fuel with good precision and accuracy. The root-mean-square error of calibration ranged from 0.1 to 0.5°C, and was typically below ~0.2°C, for the PLS calibration of the ADC modeling with GC  $\times$  GC-TOFMS data, indicating a good fit of the model to the calibration data.

Partial least squares analysis of rocket propulsion fuel data using diaphragm valve-based comprehensive two-dimensional GC coupled with flame ionization detection introduced a new method for comprehensive GC  $\times$  GC separations with application of high-temperature diaphragm valves for in-oven modulation for GC  $\times$  GC, providing an alternative to other GC  $\times$  GC methods that used cryogenic fluids and MS [192]. For comparison, using PLS analysis, the GC  $\times$  GC-FID (flame-ionization detector) signal of the entire 2D separations was regressed against the same ASTM values, yielding a linear trend for the three compound classes (alkanes, cycloalkanes,

and aromatics). A more detailed PLS analysis was undertaken of the compounds classes (*n*-alkanes, *iso*-alkanes, mono-, di-, and tri-cycloalkanes, and aromatics), and of physical properties previously determined by ASTM methods (such as net heat of combustion, hydrogen content, density, kinematic viscosity, sustained boiling temperature and vapor rise temperature). Results from these PLS studies using the relatively simple and inexpensive GC  $\times$  GC-FID instrumental platform were compared with previously reported results using the GC  $\times$  GC-TOFMS instrumental platform.

Improvements in the method and apparatus used for the measurement of distillation curves for complex hydrocarbon fluid mixtures included the addition of a composition-explicit channel of data, improved temperature control and measurement, and improved and less uncertain volume measurement [179]. The improved approach was applied to two complex hydrocarbon fluids, RP-1 and a synthetic JP-8 that was designated as S-8. Modern versions of RP-1 are produced from a narrow-range kerosene fraction that is processed to reduce unsaturated compounds and also sulfur-containing hydrocarbons. S-8 is a synthetic substitute for fluids such as JP-8 and Jet-A. It is produced with the Fischer-Tropsch process from natural gas. As these new and reformulated fluids gain increasing application, especially in aviation/aerospace, it will be increasingly important to have material characterization test procedures that are reproducible and that have a sound and fundamental basis. This will allow modeling of the properties and guide further refinement of these fuels. GC-MS-IR analysis of RP-1, RP-2, and TS5 and showed 20–30 major peaks that were all identified and listed in a table with their retention times and CAS RN numbers for further identification [183].

### 3.4.3 Distillation Curves

It is common practice to characterize the boiling temperature range of hydrocarbon mixtures by distillation curves, measuring the fraction of a sample that has distilled over in specific temperature ranges. These methods are specified in ASTM D86.

The compositional variability of 11 orthogonal batches of RP-1 that were prepared to represent the range of formulation recipes was assessed with ADC metrology [181, 182]. This method is an improvement of classical boiling curve techniques. The temperature grid of the ADC was used to conclude that the variabilities of RP-1 and RP-2 are significant, and perhaps higher than expected.

## 3.5 Thermal Stability of RP-1

Carbon deposition in cooling channels of LOX/RP-1 engines has been a problem for a long time, but because these engines in expendable launch vehicles were used only once, little effort was made to correct this situation [193]. It was only when launch vehicles became reusable that the coke deposition problem got serious attention.

A laboratory-scale flow reactor was developed to subject small amounts (approximately 1 mL) of deoxygenated fuels to controlled conditions of temperature and residence-time-at-temperature at constant pressure (34 atm) in the liquid or supercritical phase [54]. The reactor was made from 316 stainless steel HPLC tubing. Using an in-line analytical system and off-line chromatographic analysis of products, the thermal stability of the parent material, as well as the thermal fragmentation products of each fuel, was measured. Some of the candidate materials tested showed only marginal thermal stability with major decomposition occurring before 673 K (400 °C; ~3 s residence time). Other fuels (JP-10, RP-1, RG-1, RJ-6, and RJ-7) showed excellent thermal stability with little decomposition even at 873 K (600 °C). Results showed the pyrolytic stability of candidate materials relative to each other, and provided insights into the mechanisms of thermal decomposition for specific fuel candidates.

A series of electrically heated tube tests was performed at the NASA Glenn Research Center's Heated Tube Facility to investigate the effects that sulfur content, test duration, and tube material may have on the overall thermal stability and materials compatibility characteristics of RP-1 [194]. Scanning-electron microscopic (SEM) analysis, in conjunction with EDS, was used to characterize the condition of the tube inner wall surface and any carbon deposition or corrosion formed during these runs. Results of the parametric study indicated that tests with standard RP-1 (total sulfur ~23 ppm) and pure copper tubing were characterized by a deposition/deposit shedding process, producing local wall temperature swings as high as 278 K (500 °F). The effect of this shedding was to keep total carbon deposition levels relatively constant for run times from 20 min up to 5 h, though increasing tube pressure drops were observed in all runs. Reduction in the total sulfur content of the fuel from 23 ppm to <0.1 ppm resulted in the elimination of deposit shedding, local wall temperature variation, and the tube pressure drop increases that were observed in standard sulfur level RP-1 tests. Results of the study were consistent with previously published heated tube data that indicated that small changes in fuel total sulfur content can lead to significant differences in the thermal stability of kerosene type fuels and their compatibility with copper-based materials. In conjunction with the existing thermal stability database, these findings provided insight into the feasibility of cooling a long-life, high-performance, high-pressure liquid rocket combustion chamber and nozzle with RP-1 or RP-2.

The global decomposition kinetics of RP-1 were investigated by measuring the decomposition of RP-1 at elevated temperatures (that is, under thermal stress) as a function of time and then deriving a global pseudo-first-order rate constant that described the overall mixture decomposition [195]. Although not as rigorous as a component-by-component kinetics analysis, this approach was nevertheless considered instructive and can be used to guide the aforementioned property measurements. Decomposition measurements were made at 648, 673, 698, and 773 K (375, 400, 425, and 500 °C) for two separate samples of RP-1. One sample was a typical batch, showing the expected fractions of paraffins, cycloparaffins, olefins, and

aromatics. The other was an off-specification batch that had unusually high olefin and aromatic contents. Decomposition rate constants ranged from  $6.92 \times 10^{-5} \text{ s}^{-1}$  at 648 K (375 °C) to  $1.07 \times 10^{-3} \text{ s}^{-1}$  at 773 K (500 °C). Although the primary purpose of this work was to establish operating ranges for the property measurements, the results clearly have implications in other facets of RP-1 applications. These applications include establishing operating ranges for supercritical fluid heat sink regimes, setting residence times in cooling channels of engines, and similar applications. In addition to the study of decomposition kinetics, a chemical analysis was done of the vapor phase that was produced upon thermal stress.

The effects of fuel composition changes on rocket fuel thermal stability were experimentally investigated [196]. A High Reynolds Number Thermal Stability test device was used to evaluate thermal stability of JP-8 and RP-1 fuels. The experiment consisted of an electrically heated, stainless steel capillary tube with a controlled fuel outlet temperature. An optical pyrometer monitored the increasing external temperature profiles of the capillary tube as deposits build inside during each test. Multiple runs of each fuel composition provided results on measurement repeatability. Testing at two different facilities provided data on measurement reproducibility. The technique was able to distinguish among standard RP-1 rocket fuels and those having reduced sulfur levels. Carbon burn-off analysis of residue in the capillary tubes on the RP-1 fuels correlated well with the external temperature results.

The thermal decomposition of RP-1, RP-2, and mixtures of RP-2 with three different additives has been investigated [197]. The mixtures with RP-2 contained 5% 1,2,3,4-tetrahydronaphthalene (tetralin), 5% 1,2,3,4-tetrahydroquinoline (THQ), or 256 mg/l of the additive used to make JP-8+100. Decomposition reactions were performed in stainless steel ampoule reactors at temperatures from 648 to 723 K (375 to 450 °C). All of the reactions were run with an approximate initial pressure of 34.5 MPa (5000 psi). After each reaction the thermally stressed liquid phase was analyzed by GC. For RP-1 and RP-2, the increase in a suite of light decomposition products was used to derive global, pseudo-first-order rate constants that approximated the overall rate of decomposition. For RP-2, decomposition rate constants ranged from  $1.33 \times 10^{-5} \text{ s}^{-1}$  at 648 K (375 °C) to  $5.47 \times 10^{-4} \text{ s}^{-1}$  at 723 K (450 °C). The rate constants for RP-1 decomposition were not significantly different [198]. The addition of THQ and tetralin had a significant effect on the decomposition of RP-2. Compared with neat RP-2, the addition of 5% THQ slowed the decomposition by an order of magnitude, whereas the addition of 5% tetralin slowed the decomposition by approximately 50%.

An apparatus was designed that would subject flowing hydrocarbons to thermal stresses similar to those experienced in regenerative cooling channels of rocket engines [199]. The volatility of thermally stressed samples of RP-1 and RP-2 rocket propellant kerosenes was measured by use of an ADC method [200]. Measuring the properties of thermally stressed kerosene was motivated by the use of kerosenes as a coolants prior to combustion in the engines. Samples of RP-1 and RP-2 were stressed at 748 and 783 K (475 and 510 °C), at a pressure of 17 MPa (2500 psi), for residence times of 0.5 min.

Volatility measurements revealed significant changes early in the distillation curves, becoming very pronounced at the higher temperature. The volatility measurements were supplemented with chemical analyses and a calculation of the enthalpy of combustion as a function of the distillate volume fraction. It was noted that the increase in volatility can be explained by the significant increase of very light (lower molecular mass) components produced during the thermal stress. It was noted that the enthalpy of combustion followed the same pattern as the volatility, the same as what was reported in previous studies.

Measurements of fuel decomposition and ethylene evolution time histories during decomposition of RP-fuel vapors and their possible surrogate components were carried out between 1000 and 1500 K in two shock tubes, the Aerosol Shock Tube, for experiments between 4 and 8 atm, and the High Pressure Shock Tube, for experiments between 18 and 51 atm [201–203]. From these measurements, overall fuel decomposition rates for six fuels (RP-1, RP-2, JP-7, *n*-dodecane, methylcyclohexane, and *iso*-cetane) were determined and ethylene yields for four of these fuels (RP-1, *n*-dodecane, methylcyclohexane, and *iso*-cetane) were determined. An RP-1 decomposition surrogate was formulated based on three targets: compound class, overall fuel decomposition rate, and ethylene yield. This resulted in a surrogate containing 32% *n*-dodecane, 59% methylcyclohexane, and 9% *iso*-cetane, which would closely resemble RP-1. The activation energies of kerosene decomposition are summarized in Table 26.

**Table 26:** Activation energies of kerosene decomposition.

| Fuel               | $E_a$<br>kJ/mol | Temperature range<br>K | Pressure range<br>atm |
|--------------------|-----------------|------------------------|-----------------------|
| <i>n</i> -Dodecane | $213 \pm 15$    | 1110–1500              | 4–46                  |
| RP-1               | $263 \pm 7$     | 1000–1370              | 4–51                  |
| RP-2               | $250 \pm 23$    | 1050–1370              | 6.4–7.6               |
| JP-7               | $287 \pm 19$    | 1080–1180              | 4.5–5.2               |

| <i>iso</i> -Cetane | 244             | 990–1240               | 20.3–22.5             |

Data source: [201,202]

Measurements were made at ambient pressure of the thermophysical properties density, velocity of sound, and viscosity, and the derived property adiabatic compressibility, for the same thermally unstressed and stressed RP-1 and RP-2 fuel samples [204]. The reactor that was built to thermally stress the fuels had been described in detail elsewhere [199]. The fuel was pressurized by use of a high-pressure syringe pump and then delivered to a high-temperature reactor capable of generating controlled temperatures up to 873 K (600 °C). Downstream of the reactor, the fluid was delivered to a chilled water bath heat exchanger to cool the fluid and quench any further decompo-

sition reactions. The cooled fluid was then directed through a back-pressure regulator and into a collection vessel. The combination of the syringe pump and back-pressure regulator allowed the operator to control the residence time of the fluid in the reactor by providing controlled, constant flow rates at a wide range of nominal pressures. For this work, the RP-1 and RP-2 samples were both thermally stressed for 0.5 ( $\pm 0.05$ ) min at a constant pressure of 17 ( $\pm 0.1$ ) MPa and at two temperatures, 748 and 783 K (475 and 510 °C). Density, velocity of sound, and viscosity were measured for samples of RP-1 and RP-2 that had been stressed for 0.5 min. at 748 and 783 K (475 and 510 °C) at a pressure of 17 MPa. Density and velocity of sound were measured from 278 to 323 K (5 to 50 °C) for samples stressed at 748 K (475 °C) and from 278 to 308 K (5 to 35 °C) for samples stressed at 783 K (510 °C). Viscosity was measured from 263 to 323 K (−10 to +50 °C) and 263 to 308 K (−10 to +35 °C) for the samples stressed at 748 and 783 K (475 and 510 °C) respectively. All measurements were made at ambient atmospheric pressure ( $\sim 83$  kPa). The densities of stressed samples were lower than those of the unstressed samples. For both RP-1 and RP-2, the densities of the thermally stressed samples were lower relative to their respective unstressed samples, but the magnitudes of those decreases in density were different for the two fuels. For RP-1, the two thermally stressed samples had similar densities. In contrast to RP-1, the thermally stressed RP-2 samples had densities that were more significantly different from one another, varying by 0.4% at 278 K (5 °C) and 0.6% at 308 K (35 °C). Consequently, relative to unstressed RP-2, RP-2-TS-475 had densities that were 0.8–0.9% lower and RP-2-TS-510 had densities that were 1.2–1.4% lower. As RP-1 and RP-2 decompose, the concentrations of smaller, more volatile molecules increase. The sound speeds of the thermally stressed samples were lower relative to their respective unstressed samples for both RP-1 and RP-2. Relative to unstressed RP-2, RP-2-TS-475 had sound speeds that were 1.2–1.6% lower and RP-2-TS-510 had sound speeds that were 3.2–3.7% lower. For both RP-1 and RP-2, the dynamic viscosities of the thermally stressed samples were considerably lower relative to their respective unstressed samples, with the TS-510 samples showing the most significant deviations. RP-1-TS-475 values were 12–14% lower than unstressed RP-1, and RP-1-TS-510 values were 38–39% lower. Relative to unstressed RP-2, RP-2-TS-475 had dynamic viscosities that were 15–17% lower and RP-2-TS-510 had values that were 40–41% lower.

During regenerative cooling in rocket engines, the extreme temperatures can have significant effects on the fuel composition. Extreme temperatures can result in coking and the fouling of cooling channels. In addition, the decomposition of the fuel can lead to changes in the fuel properties that can affect the fuel performance. Thermally stressed RP-1 and RP-2 were generated at two temperatures, 748 and 783 K (475 and 510 °C) and thermophysical property measurements were performed to characterize the resulting fluids [205]. The measurements included chemical composition, thermal decomposition reaction rate constants, volatility, density, velocity of sound, adiabatic compressibility, dynamic viscosity, and kinematic viscosity. There was a significant increase in volatility with thermal stress, the effect at 783 K (510 °C) being more strik-

ing, with the production of a significant dissolved gaseous fraction. For the other properties (except for adiabatic compressibility) there was a decrease in the respective properties with thermal stress.

The change in fuel composition and molecular structure after passing through the regenerative cooling channels of a rocket engine may have a significant impact on heat release, flame propagation, and mass burning rates in these highly turbulent combustion systems stemming from modifications to fuel chemistry and molecular/thermal diffusivity. Therefore, the effect of endothermic reactions on the subsequent combustion behavior of the reacted (thermally stressed) fuel mixture was experimentally examined [206]. The objective of the study was to investigate: **(1)** the degree of thermal decomposition that a fuel can experience when used in a typical regenerative cooling system at high pressure and temperature; and **(2)** the impact that this thermal decomposition has on fundamental combustion properties for three hydrocarbon model fuels selected as surrogates for RP-1: *n*-heptane, *n*-dodecane, and Jet A. A counterflow flame burner was used to investigate the extinction strain rates of neat *n*-heptane, *n*-dodecane, and Jet A.

The pyrolysis of RP-1 was investigated by reactive molecular dynamics simulations with ReaxFF force field [207]. The initial reactivity differences between a three-component surrogate model and a more complex 24-component model were observed in a series of heat-up and isothermal pyrolysis simulations performed using the GPU-enabled computer code GMD-Reax. The RP-1 conversion in the three-component surrogate was slower than that of the 24-component model. The maximal weight fraction difference for RP-1 consumption can be up to 21.2% in heat-up simulations and 22.3% in isothermal simulations. The reaction analysis facilitated by the code VARxMD further revealed the differences in pyrolysis intermediates, products, and reaction pathways between the two RP-1 models. Normal paraffin reactions of the two RP-1 models were similar owing to the similar fuel structures of normal alkanes. For branched paraffin reactions, the pyrolysis of the multi-branched fuel component of *iso*-cetane in the three-component surrogate produces 2-methylpropene, which is not a major pyrolysis product in the 24-component model, mainly owing to a lack of quaternary carbon with methyl side chains in the branched paraffin components. Compared with the reactions of methylcyclohexane, the only cycloparaffin in the three-component surrogate, more versatile ring opening reactions of cycloparaffins can occur in the 24-component model that will generate more dienes and cyclohexene from the double-ring fuel structures. The results suggested that the reactive molecular dynamics simulations of multi-component model with rich chemical structures closer to real fuel components have the potential as an alternative approach for evaluating reactivity in fuel pyrolysis.

### 3.6 Materials Compatibility with RP-1

Materials compatibility of hydrocarbon fuels (Mil-Spec RP-1, *n*-dodecane, propane, and methane) in contact with copper-based combustion chamber liner materials (OFHC, NASA-Z, and ZrCu coppers) was tested using two different methods [208]. Static tests, in which copper coupons were exposed to fuel for long durations at constant temperature and pressure, provided compatibility data in a precisely controlled environment. Dynamic tests, using the Aerojet Carbothermal Test Facility, provided fuel and copper compatibility data under realistic booster engine service conditions. Tests were conducted using very pure grades of each fuel and fuels to which a contaminant, e.g., ethylene or methyl mercaptan, was added to define the role played by fuel impurities. It was found that each of the copper materials exhibited similar compatibility behavior. However, there were significant differences among the various hydrocarbon fuels tested. In RP-1, carbon deposits were formed above  $T_{\text{wall}} = 578 \text{ K}$  (580 °F) and copper corrosion was observed with sulfur contents above 50 ppm. The result of this deposition process was the formation of a chemically complex, thin, but very tenacious, tar on all exposed copper surfaces. This tar inhibited heat transfer, but had little effect on the flowrate or pressure drop through the channel during the dynamic tests. Copper(I) sulfide is the corrosion product. This corrosive process roughened the copper surfaces, and substantially increased the pressure drop through the cooling channel. It did not have a major impact on the heat-transfer characteristics of the channel. Protective gold or platinum coatings were evaluated to prevent both carbon deposits and copper corrosion. RP-1 was much more stable in Hastelloy-X than in NASA-Z alloy. Additional work was performed under an extension of this contract [209, 210].

### 3.7 Safety Properties of RP-1

#### 3.7.1 Flammability of RP-1 Vapors in Air

Because the content of light boiling hydrocarbons in RP-1 may vary, it is difficult to exactly determine generally valid numbers for flash point and limits of flammability in air. It varies widely from sample to sample.

#### 3.7.2 Suppression of Flammability of RP-1

Experimental studies were carried out to determine the quantities of helium, nitrogen, carbon dioxide, and/or trifluorobromomethane needed for suppressing ignition of mixtures of oxygen with RP-1 under conditions of turbulent flow in a tube measuring 15 cm (6 in) in diameter [211]. The results indicated that on a weight basis the order of effectiveness of the various agents was  $\text{He} \gg \text{N}_2 > \text{CF}_3\text{Br} > \text{CO}_2$  for RP-1. The quantities of agents required were large enough to preclude widespread in-flight applications to

inert leakage once it is detected. The principal utility of inerting processes is probably only in connection with fire prevention during static firing and prelaunch operations on the ground.

### 3.8 Gelled Kerosene RP-1

#### 3.8.1 Metallized Gelled RP-1

##### 3.8.1.1 Aluminized Gelled RP-1

Aluminum slurries in kerosenes have been tested as rocket propellants since the early 1930s (see Section 2.12.3). The types of kerosenes were not very well characterized in those early years. Probably, more testing has been done with aluminized undefined kerosenes and JP-4 than with RP-1. The work described in the following references was done specifically with gelled RP-1. There have not been any flight applications of metallized RP-1.

Fumed silica as a gelling agent is not readily wetted by kerosene and conventional kitchen-type rotary mixers do not give uniform gels. Improved dispersion of gellant and added metal powder were achieved with resonant acoustic mixing [212]. The rheology and high-g centrifuge stability of kerosene gelled with EH-5 fumed silica and metallized with nano-aluminum L-Alex<sup>®</sup> powder were measured with different gelling agent loadings, but mostly the same metal loading of ~30%. A surfactant was used to help wet the nanoparticles to aid in the uniform dispersion in the gelled propellant.

The rheological behavior of gelled RP-1 and JP-8 with fumed silica as a gelling agent has been measured and an optimal mixing process has been selected [213]. The rheological parameters of the gelled kerosene showed a significant influence of the added amount of silica in comparison with the ungelled pure liquids (Figure 22). Similar measurements were made with JP-8 instead of RP-1.

The rheology and droplet burning behaviors of RP-1 gelled with fumed silica were compared with those of MMH gelled with hydroxypropyl cellulose [129]. Droplets of gelled MMH burning in air swelled and had a flexible droplet surface, whereas burning kerosene droplets gelled with fumed silica had a rigid silica structure that remained unburned.

Gelled RP-1 has been used to study the rheological behavior of gelled hydrocarbons using 4–7 mass-% of fumed silica as the gelling agent [113]. Viscosity, stability, thixotropic behavior, and the viscoelastic properties of the gel through their storage and loss moduli were measured as a function of the amount of gelling agent added. Differential scanning calorimetry measurements showed only a slight influence of the gelling-agent amount on the enthalpy of vaporization of the gels. The ungelled hydrocarbons had a higher enthalpy of vaporization than the gels.

Fumed silica, also known under the trade name Cab-O-Sil<sup>®</sup>, is a useful gelling agent for fuels as well as oxidizers. The rheological behavior of gelled JP-8 turbine fuel

**Figure 22:** Viscosity of gelled RP-1 as a function of shear rate and silica amount. (Reproduced and modified from [213] with permission dated 11-Feb-2021.)

and gelled rocket propellant RP-1 with fumed silica as a gelling agent was measured and the optimal gel mixing process, gel stability, and rheological parameters showed a significant influence of the added silica amount [127, 128].

### 3.8.1.2 Nano-Aluminum in Metallized RP-1 Gels

A constant volume bomb was used to measure the ignition delay of nano-aluminum metallized RP-1 injected into the air-filled bomb containing air at controlled temperature and pressure [214]. Time was measured from the first movement of the piston injecting the fluid into the chamber to the first noticeable pressure rise. The ignition delay times were measured for RP-1 with and without various amounts of added aluminum and at different temperatures, pressures, and gas compositions in the bomb.

Aluminum as an additive to fuels is a highly energetic metal that can react with a wide variety of oxidizers to produce propellants with a high specific impulse. When added to kerosene rocket fuel, aluminum substantially increases theoretical volumetric density  $I_{sp}$ , potentially reducing the size of tankage and overall system weight. However, depending on the particle size, aluminum tends to agglomerate in burning liquid hydrocarbon droplets, delaying combustion within the engine, reducing the delivered performance. Gels were formulated of 0, 25, 30, and 55 mass-% Alex<sup>®</sup> nano-aluminum powder suspended in RP-1 using a combination of wetting and gelling agents [215, 216]. The viscosities of such gels was measured as a function of aluminum content, temperature, and shear rate and were found to be non-Newtonian, so-called yield-pseudoplastic. At loadings greater than 30 mass-% Alex<sup>®</sup> no additional gellant was necessary to achieve dynamic stability as measured

by centrifuging the gels at 1300 rpm for 1 h. In contrast, micron size aluminum gels required 5% fumed silica as a gellant to achieve dynamic stability, as did the gels containing only 5% Alex<sup>®</sup>. Ignition delay of Alex<sup>®</sup>/RP-1 gels were determined in a laboratory bomb over the temperature range 673–873 K (400–600 °C) and compared with RP-1 gels without any aluminum and with neat RP-1. The data showed that nano-aluminum could be completely consumed during the interval of spraying in a short laboratory bomb. Moreover, the combustion of Alex<sup>®</sup> accelerated the ignition of the RP-1.

### 3.9 Applications of RP-1

There are dozens of launch vehicles that have used or are currently using RP-1 or its low-sulfur derivative RP-2 as the standard storable hydrocarbon fuel. On more than one occasion there were attempts to formulate hydrocarbon fuels that might have advantages over either RP-1 or RP-2, and lead to a gradual replacement of these fuels.

## 4 Rocket-Grade Kerosene RP-2

### 4.1 Physical Properties of RP-2

Physical properties of RP-1 and RP-2 were measured and are now available on-line in the NIST Reference Fluid Thermodynamic and Transport Properties (REFPROP) computer program [158].

#### 4.1.1 Density of RP-2

The density of RP-2 has been measured with a density and sound speed analyzer DSA 5000, Anton-Paar Corporation, at ambient (0.083 MPa) pressure and compressed liquid density measurements were made with a fully automated densimeter at elevated pressures between 0.083 and 40 MPa [163, 164]. The density of RP-2 as a function of temperature and pressure is illustrated in Figure 23. The solid circle high-pressure data points are for pressures between 0.5 and 40 MPa.

The density of RP-2 at atmospheric pressure can be calculated from the equation:

$$\rho = 288.12529 \times 0.53412256^{-\left[1 + \left(\frac{1-T}{575.46086}\right)^{0.62514441}\right]}$$

where  $\rho$  is the density in kg/m<sup>3</sup> and  $T$  is the temperature in kelvin.

The density of two RP-2 samples was measured at temperatures up to 573 K and pressures up to 100 MPa [217]. A high-temperature, high-pressure (HTHP) variable volume, windowed densimeter was used to determine the density. The experimental den-

**Figure 23:** Density of RP-2 as a function of temperature and pressure. (Modified from [163].)

sity data were satisfactorily correlated by the modified Tait equation that provided a means for interpolating the density within the experimental conditions investigated in this study. The lines in Figure 24 show the fit of the Tait correlation to the experimental data. The HTHP perturbed-chain statistical associating fluid theory, Peng–Robinson (PR), and HTHP volume-translated PR equations of state were used to model RP-2 density over the entire temperature and pressure ranges. The densities of the two RP-2 samples were compared and contrasted with those reported by Outcalt et al. (2009) to highlight the impact of compositional differences on the observed RP-2 densities.

#### 4.1.2 Velocity of Sound and Compressibility of RP-2

The velocity of sound of RP-2 was measured with a density and sound speed analyzer DSA 5000, Anton-Paar Corporation, at ambient (0.083 MPa) pressure [163, 164]. The velocity of sound of RP-1 and RP-2 as a function of temperature is illustrated in Figure 7 (in the section on RP-1). The temperature dependence of the velocity of sound of RP-2 can be expressed by the polynomial equation:

$$v = 2809.8695 - 6.2215696 T + 3.9342693 \times 10^{-3} T^2$$

**Figure 24:** Density of RP-2A as a function of temperature and pressure. (Reprinted and modified from [217], with permission from ©2019 Elsevier; permission conveyed through RightsLink.)

where  $v$  is the velocity of sound in m/s and  $T$  is the temperature in kelvin. Adiabatic compressibilities in liquids can be calculated from sonic velocity data with the aid of the following equation:

$$\beta_a = \frac{1}{\rho c^2}$$

where  $\beta_a$  is the adiabatic compressibility in  $\text{m}^2/\text{N}$ ,  $\rho$  is the density in  $\text{g}/\text{m}^3$ , and  $c$  is the velocity of sound in m/s. The adiabatic compressibility of RP-1 and RP-2 was already illustrated in Figure 8 (above).

#### 4.1.3 Vapor Pressure of RP-2

There is a lack of vapor pressure data on RP-1 and RP-2. Vapor pressure of these kerosenes varies widely depending on composition of the mixture of up to 100 different hydrocarbons.

#### 4.1.4 Viscosity of RP-2

The viscosity of an RP-2 sample has been measured in an open gravitational capillary viscometer at ambient atmospheric pressure from 293 to 373 K [163, 164] (Table 27 and Figure 14).

Expanding on earlier viscosity measurements of rocket propellants from 293 to 373 K at atmospheric pressure, the viscosity of RP-2 was measured at temperatures from 270 to 425 K and at pressures up to 137 MPa using an oscillating-piston viscometer [169] (Figure 25). The pressure was changed in increments of 10 MPa between 10 and 130 MPa. The instrument was modified and recalibrated at the National Institute of

Table 27: Viscosity of RP-2.

Standards and Technology with *n*-dodecane as a known reference fluid over the full temperature and pressure range. Based on the recalibrations, the repeatability of the measurements was found to be approximately 3%, whereas the uncertainty of the instrument was estimated at 5%. The measured viscosities of RP-2 were compared with values calculated with a five-component surrogate mixture model developed

at the National Institute of Standards and Technology. The experimental data have a stronger pressure dependence than the mixture model and are up to 29% higher at high compressions.

#### 4.1.5 Heat-Transfer Coefficient of RP-2

Heat-transfer characteristics of RP-2 experiments were conducted at the Air Force Research Laboratory's HHFF, located at Edwards AFB, CA [218]. The HHFF was designed to explore many fuel-related rocket engine design considerations (e.g., high aspect ratio cooling channels, various fuel thermal stability issues, material compatibility, heat-transfer capability, effects related to dissolved oxygen or specific sulfur species contained within the fuel, etc.). The Air Force has been studying RP-2 (ultra-low sulfur RP-1) to establish an accurate baseline for future experiments in the HHFF. These initial experiments were conducted using low overall heat fluxes and wall temperatures. Results from these experiments demonstrated the facility's ability to produce repeatable data sets, as well as to maintain a constant heat source temperature throughout the test.

The heat-transfer characteristics of RP-2 were examined in the AFRPL HHFF under conditions simulating those encountered in the cooling channels of a real rocket engine [219]. Short-duration thermal stressing tests provided heat-transfer information that closely followed existing empirical correlations for RP-1. Effects of wall temperature, bulk temperature, and flow rate on heat transfer were observed and were consistent with expected behavior. The heat flux increased with increasing wall temperatures (Figure 26).

Average convective heat-transfer coefficient was measured for several short-duration tests, and non-dimensionalized heat transfer (Nusselt number) was compared with an existing empirical correlation for RP-1. Good agreement with the correlation was seen when the experimental data were corrected for inner (wetted) wall temperature, which was shown to vary substantially around the circumference of the tube wall. Longer-duration tests at elevated wall temperatures provided the first steps in identifying the conditions under which solid carbon deposits may form.

The AFRL HHFF simulates cooling channel conditions in a subscale environment [220]. It operates at up to 31 MPa (4500 psi) channel pressure, 480 K (400 °F) bulk fluid temperature,  $>0.075$  kg/s ( $>10$  lb<sub>m</sub>/min.) flow rate, 870 K (1100 °F) wall temperature with 25 PID-controlled heaters that maintain the block temperature. It also has O<sub>2</sub> sparging capability, vacuum environment simulation, and can operate for long test durations at high heat fluxes. Following each test the test section is segmented into 2.5-cm (1-in.) segments that are individually examined under the microscope and analyzed for coke deposition.

A series of electrically heated tube tests were performed at NASA GRC's Heated Tube Facility to investigate the thermal stability and heat transfer of RP-2 as a fuel for

**Figure 26:** Average tube heat flux as a function of wall temperature for short duration tests in copper tube at varying flow conditions. (Reproduced and modified from [219].)

next-generation regeneratively cooled, reusable hydrocarbon boost engines [221]. The effects of duration, operating condition and test piece material on the overall thermal stability and materials compatibility characteristics of RP-2 were evaluated using copper and 304 stainless steel test sections. The copper tests were run at a pressure of 6.8 MPa (1000 psia), heat flux up to 9.8 MW/m<sup>2</sup> (6.0 BTU in.<sup>-2</sup> s<sup>-1</sup>), and wall temperatures up to 911 K (1180 °F). Preliminary results, using measured wall temperature as an indirect indicator of the carbon deposition process, showed that in copper test pieces above approximately 728 K (850 °F), RP-2 begins to undergo thermal decomposition resulting in local carbon deposits. Wall temperature traces showed significant local temperature increases followed by near instantaneous drops, which were attributed to the carbon deposition/shedding process in previous investigations. These findings gave an insight into the feasibility of cooling a long-life, high-performance, high-pressure liquid rocket combustor and nozzle with RP-2.

A model was developed of the steady three-dimensional combined flow of fluid, heat, and electricity in an experimental apparatus designed to test the fuel thermal stability of RP-2 [222]. A numerical simulation was performed for the purposes of model validation and assessment of the detailed thermal characteristics of the apparatus. Conjugate heat transfer and electric current flow of rocket-grade kerosene (RP-2) flowing in an electrically heated tube was simulated. The model and

boundary conditions were selected so as to simulate an experimental case reported in the fuel thermal stability literature. The model included steady, incompressible, variable-density turbulent flow inside the tube, thermally coupled with steady heat conduction, and electric current flow in the solid copper apparatus. Temperature dependences of fluid and solid thermodynamic and transport properties were included in the model. The tube inner wall surface roughness was adjusted in order to match the cooling efficacy of the fuel in the simulation with that observed in the experiment. The simulation predicted an RP-2 temperature rise in agreement with the experiment, and a tube wall thermal state largely in agreement with the experiment. The simulation results were used to identify critical regions of excessive temperature, current flux density, and Joule heating concentration in the experimental apparatus. The predicted tube wall temperatures at each end of the heated portion of the tube were significantly less than the experimentally observed values. The predicted temperatures of the thermal chokes contacting the tube were considerably lower than the experimentally observed values. It was suggested that an unmodeled, unrecognized thermal resistance or resistive heating source may have been present in the experiment.

#### **4.1.6 Thermodynamic Properties of RP-2**

Thermodynamic properties of RP-2 are essentially identical to those of RP-1.

### **4.2 Chemical Properties of RP-2**

#### **4.2.1 Chemical Composition of RP-2**

The GC analytical results for RP-2 were similar to those for RP-1. There were 28 major constituents (peak area counts in excess of 1%) ranging from 2,6-dimethylnonane to *n*-hexadecane. The major constituents comprised linear and branched paraffins, and one- and two-ring cyclic paraffins containing 11-16 carbon atoms with no significant aromatic or olefin content [183]. Changes in the measurement of distillation curves for complex fluids were a significant improvement over previous approaches, featuring a composition-explicit data channel for each distillate fraction (for both qualitative and quantitative analysis) and an assessment of the energy content of each distillate fraction, among other features. The most significant modification was achieved with a different sampling approach that allowed precise qualitative as well as quantitative analyses of each fraction, on the fly. This method was applied to the measurement of a wide variety of fluids, including hydrocarbons, gasoline, jet fuel, diesel fuels (both petroleum-derived and biodiesel), and crude oils, and in particular to representative batches of RP-1, RP-2, and TS-5. Not only the distillation curves but also the composition-explicit information was used to characterize distillate cuts in terms of composition and available energy content by adding up the composite enthalpy of combustion

for each component selected for identification in each distillate fraction. The distillation curves and enthalpy data for all three fluids were very similar. Table 28 shows a comparison of composition of RP-2 and RP-1.

**Table 28:** RP-1/RP-2 comparison (ASTM D2425).

| Summarized D2425 (vol.-%) | RP-1/5235 | RP-2/5433 |
|---------------------------|-----------|-----------|
| Paraffins                 | 44        | 63        |
| Cycloparaffins            | 33        | 18        |

| Diaromatics (vol.-%)      | <0.2      | <0.2      |
| Total aromatics (vol.-%)  | <0.2      | 0.2       |
| Total saturates (vol.-%)  | >99.8     | 99.8      |

Data Source: [219,220]

#### 4.2.2 Surrogate Mixtures Representing RP-2

Because of the complexities involved in measuring and modeling the performance and properties of finished fuels, the fuel science community must often use surrogate mixtures as substitutes, especially in the absence of consensus standard mixtures. Although surrogate mixtures are often formulated on the basis of the ability of a particular mixture to reproduce a particular property, there is usually a desire to employ surrogate mixtures that are physico-chemically authentic. This means that, provided that the primary purpose is satisfied, researchers are inclined to choose mixtures that have physical and chemical properties appropriate to the finished fuel.

Surrogate hydrocarbon fuel mixture models were developed to represent the thermophysical properties of two kerosene rocket propellants, RP-2 and RP-1 [19]. The surrogates were developed with a procedure that incorporated experimental data for the density, sound speed, viscosity, thermal conductivity, and the ADCs for samples of the two fuels. The surrogate for RP-2 contained five components (numbers are molar fractions):  $\alpha$ -methyldecalin (0.354), *n*-dodecane (0.158), 5-methylnonane (0.084), 2,4-dimethylnonane (0.071), and heptylcyclohexane (0.333). Comparisons with experimental data demonstrated that the models were able to represent the density, velocity of sound, viscosity, and thermal conductivity of both fuels to within (at a 95% confi-

dence level) 0.4, 2, 2, and 4% respectively. The volatility behavior, as measured by the ADCs, was reproduced to within 0.5%.

#### 4.2.3 Specifications for RP-2

The composition of RP-2 is a sub-set of the specification for RP-1, as described in MIL-DTL-25576E [80].

#### 4.2.4 Analysis of RP-2

The list of analytical methods used for the characterization of RP-2 to verify compliance with MIL-DTL-25576E is one page long [80]. The most fundamental method used for characterization of hydrocarbon fuel blends is the distillation fraction curve, measuring the amount of distillate that has collected while the temperature in the vapor phase has been rising, and also measuring the amount of less volatile residue left behind at the upper end of the distillation range. Most of those test methods are documented ASTM test methods.

#### 4.2.5 Thermal Stability of RP-2

Thermal stability and heat transfer characteristics of RP-2 were examined in the AFRPL HHFF under conditions simulating those encountered in the cooling channels of a real rocket engine [219]. RP-2 was thermally stressed while flowing through circular copper tube test sections. Short-duration thermal stressing tests provided heat-transfer information that closely followed existing empirical correlations for RP-1. Effects of wall temperature, bulk temperature, and flow rate on heat transfer were observed and were consistent with expected behavior. Longer-duration tests at elevated wall temperatures provided the first steps in elucidating the conditions under which solid carbon deposits form. The test sections were analyzed post-test with optical and scanning electron microscopy and carbon deposition burn-off for signs of coke formation. The results from these analyses indicate the presence of solid carbon deposition for high-wall temperature tests exceeding 30 min in duration, although further testing is required to make more conclusive comparisons.

The thermal decomposition of RP-2, and mixtures of RP-2 with three different additives has been investigated [197, 223]. The mixtures with RP-2 contained 5% 1,2,3,4-tetrahydronaphthalene (tetralin), 5% THQ, or 256 mg/L of the additive used to make JP-8+100. Decomposition reactions were performed in stainless steel ampoule reactors at temperatures from 648 to 723 K (375 to 450 °C). All of the reactions were run with an approximate initial pressure of 34.5 MPa (5000 psi). After each reaction the thermally stressed liquid phase was analyzed by GC. For RP-2, the increase in a suite of light decomposition products was used to derive global, pseudo-first-order rate constants that approximated the overall rate of decomposition. The addition of THQ and tetralin had a significant effect on the decomposition of RP-2. Compared with neat

RP-2, the addition of 5% THQ slowed the decomposition by one order of magnitude, whereas the addition of 5% tetralin slowed the decomposition by approximately 50%.

The decomposition kinetics of RP-2 was studied at 648, 673, 698, and 723 K (375, 400, 425, and 450 °C) in comparison with RP-1 [198]. All of the decomposition reactions were performed in stainless-steel ampule reactors. At each temperature, the extent of decomposition as a function of time was determined by analyzing the thermally stressed liquid phase by GC. These data were used to derive global pseudo-first-order rate constants that approximate the overall rate of decomposition for the fuel. For RP-2, decomposition rate constants ranged from  $1.33 \times 10^{-5} \text{ s}^{-1}$  at 648 K (375 °C) to  $5.47 \times 10^{-4} \text{ s}^{-1}$  at 723 K (450 °C) (Figure 27). There was no significant difference between RP-1 and RP-2 in this test.

**Figure 27:** Rate constants of RP-2 thermal decomposition. (Reproduced and modified from [158].)

The activation energy derived from the slope of the Arrhenius graph shown above was  $180 \pm 30 \text{ kJ/mol}$ . One use of these rate constants is for the design and planning of physical property measurements at high temperatures. On the basis of the amount of time required for 1% of the sample to decompose ( $t_{0.01}$ ), allowable instrument residence times ranged from 15 min. at 648 K (375 °C) to 0.3 min. at 723 K (450 °C).

Hydrogen donors increase thermal stability by interrupting radical decomposition pathways. The effect of three potential stabilizing additives on the thermal decomposition of RP-2 was investigated in stainless steel reactors [224]. The additives were THQ, 1,2,3,4-tetrahydronaphthalene (tetralin), and the additive package that is used to make JP-8+100 (herein referred to as the “+100 additive”). For mixtures of RP-2

with THQ and tetralin, the concentration of additive was 5% by mass. The mixture of RP-2 with the +100 additive contained only 256 mg/L of the additive (the same concentration used to make JP-8+100). Decomposition reactions were performed at 648, 673, 698, and 723 K (375, 400, 425, and 450 °C) in stainless steel reactors. At each temperature, the extent of decomposition as a function of time was determined by analyzing the thermally stressed liquid phase using GC. The results with each additive were compared with the decomposition of neat RP-2 under the same conditions. The addition of 5% THQ slowed the rate of decomposition by approximately one order of magnitude. The addition of 5% tetralin slowed the rate of decomposition by approximately 50%. At the low concentration tested, the +100 additive did not significantly change the thermal stability of the RP-2.

The stabilizing additive THQ was identified as a potential stabilizer for RP-2, but previous tests were done at only one concentration of this additive. In order to determine the minimum effective additive level, the thermal stability of RP-2 with varying concentrations of THQ was investigated [225]. The mixtures (% by mass) were RP-2 + 0.1% THQ, RP-2 + 0.5% THQ, RP-2 + 1% THQ, and RP-2 + 5% THQ. These were thermally stressed in sealed stainless-steel reactors at 673 K (400 °C) for 1–4 h. The approximate initial pressure at the reaction temperature was 34.5 MPa (5000 psi). The extent of decomposition as a function of time was determined by analyzing the thermally stressed liquid phase using GC. The results with each THQ mixture were compared with the thermal stability of neat RP-2 under the same conditions. The thermal stability of the mixtures showed a clear dependence upon the concentration of THQ. For example, the addition of 5% THQ slowed the rate of decomposition by approximately one order of magnitude, and the addition of 0.5% THQ slowed the rate of decomposition by approximately 50%. Another potential stabilizing additive evaluated was *trans*-decahydronaphthalene (decalin). Unlike THQ, the addition of 5% decalin to RP-2 had no significant effect on the thermal stability of RP-2.

A series of tests were performed in NASA GRC's Heated Tube Facility to study the heat-transfer and thermal-stability behavior of RP-2 under conditions similar to those found in rocket engine cooling channels [226]. Using resistively heated copper tubes in a vacuum chamber, flowing RP-2 was heated to explore thermal effects under a wide range of test conditions. Wall temperature (728–839 K = 850–1050 °F) and bulk fluid temperature (422–533 K = 300–500 °F) were varied to define thermal decomposition and stability at each condition. Flow velocity and pressure were fixed at 22.8 m/s (75 ft/s) and 6.8 MPa (1000 psia) respectively. Five different batches of RP-2 were tested under identical conditions to examine any thermal-stability differences resulting from batch-to-batch compositional variation. Among these tests was one with the potential coke reducing additive THQ. Although pure copper tubes were used for the majority of tests, two exploratory tests were performed with a copper alloy known as GRCo-42. Each tube was instrumented with 15 thermocouples to examine the temperature profile, and carbon deposition at each thermocouple location was determined post-test in an oxidation furnace. In many tests, intermittent local temperature increases were

observed visually and in the thermocouple data. These hot spots did not appear to correspond to a higher carbon deposition.

Measurements were made at ambient pressure of the thermophysical properties density, velocity of sound, and viscosity, and the derived property adiabatic compressibility, for the same thermally unstressed and stressed RP-2 fuel samples [204]. The fuel was pressurized by use of a high-pressure syringe pump and then delivered to a high-temperature reactor capable of generating controlled temperatures up to 873 K (600 °C). Downstream of the reactor, the fluid was delivered to a chilled water bath heat exchanger to cool the fluid and quench any further decomposition reactions. The cooled fluid was then directed through a back-pressure regulator and into a collection vessel. The combination of the syringe pump and back-pressure regulator allowed the operator to control the residence time of the fluid in the reactor by providing controlled, constant flow rates at a wide range of nominal pressures. For this work, the RP-2 samples were thermally stressed for 0.5 ( $\pm 0.05$ ) min at a constant pressure of 17 ( $\pm 0.1$ ) MPa and at two temperatures, 748 and 783 K (475 and 510 °C). Density, velocity of sound, and viscosity were measured for samples of RP-2 that had been stressed for 0.5 min at 748 and 783 K (475 and 510 °C) at a pressure of 17 MPa. Density and velocity of sound were measured from 278 to 323 K (5 to 50 °C) for samples stressed at 748 K (475 °C) and from 278 to 308 K (5 to 35 °C) for samples stressed at 783 K (510 °C). Viscosity was measured from 263 to 323 K (−10 to +50 °C) and 263 to 308 K (−10 to +35 °C) for the samples stressed at 748 and 783 K (475 and 510 °C) respectively. All measurements were made at ambient atmospheric pressure ( $\sim 83$  kPa). The densities of stressed samples were lower than those of the unstressed samples. For both RP-1 and RP-2, the densities of the thermally stressed samples were lower relative to their respective unstressed samples, but the magnitudes of those decreases in density were different for the two fuels. For RP-1, the two thermally stressed samples had similar densities. In contrast to RP-1, the thermally stressed RP-2 samples had densities that were more significantly different from one another, varying by 0.4% at 278 K (5 °C) and 0.6% at 308 K (35 °C). Consequently, relative to unstressed RP-2, RP-2-TS-475 had densities that were 0.8–0.9% lower and RP-2-TS-510 had densities that were 1.2–1.4% lower. As RP-2 decomposed, the concentrations of smaller, more volatile molecules increased. The sound speeds of the thermally stressed samples were lower relative to their respective unstressed samples for both RP-1 and RP-2. Relative to unstressed RP-2, RP-2-TS-475 had sound speeds that were 1.2–1.6% lower and RP-2-TS-510 had sound speeds that were 3.2–3.7% lower. For both RP-1 and RP-2, the dynamic viscosities of the thermally stressed samples were considerably lower relative to their respective unstressed samples, with the TS-510 samples showing the most significant deviations. Relative to unstressed RP-2, RP-2-TS-475 had dynamic viscosities that were 15–17% lower and RP-2-TS-510 had values that were 40–41% lower.

In order to identify compositional changes that could improve the thermal stability of RP-2, the effect of different types of alkanes on the thermal stability of RP-2 was investigated [227]. The proportion of linear, branched, or cyclic alkanes was in-

creased by mixing RP-2 with one of the following alkanes (25% by mass): *n*-dodecane, *n*-tetradecane, 4-methyldodecane, 2,6,10-trimethyldodecane, or 1,3,5-triisopropylcyclohexane. These mixtures were thermally stressed in stainless steel ampule reactors at 673 K (400 °C, 752 °F) for up to 4 h. After each reaction, the stressed fuel was analyzed by GC with flame ionization detection. The decomposition kinetics of each added alkane was determined from the decrease in its chromatographic peak. The overall decomposition kinetics of each fuel mixture was determined from the increase in a suite of chromatographic peaks that correspond to light, liquid phase decomposition products. These data are compared with similar data for neat RP-2.

As of 2014, there existed no standardized test methods to quantify the thermal stability of a kerosene fuel. Advancements in fuel processing, analysis, and thermal performance testing have provided insight into the conditions, influences, and pathways of troublesome fuel thermal decomposition in liquid rocket engine cooling systems. Multiple parameters have been identified or suggested/suspected to influence fuel thermal stability. These include overall fuel chemical composition in terms of hydrocarbon classes, the role of specific fuel constituents such as additives (beneficial) and contaminants (detrimental) on deposit formation, the effect of compositional variability on system-level cooling performance, primary fluid and thermal effects (e.g., pressure, surface temperature, etc.) determining the limitations of fuel use for a given application or environment, and coolant channel surface material composition, roughness, and treatment. Existing standard test methods are incapable of replicating the operating environments of cooling systems for advanced engines, and operational thermal stability tests are often accompanied by high associated costs and relatively long turnaround times. The proposed Compact Rapid Assessment of Fuel Thermal Integrity (CRAFTI) test methods are envisioned to be included in future fuel detail specifications for thermal performance requirements.

## 5 Chinese Aviation-Grade Kerosene RP-3

Kerosene RP-3 is used mainly in China for air-breathing turbine jet and ramjet engine propulsion. It is not known as a rocket propellant. This type of kerosene was repeatedly referred to as an “endothermic fuel.” It is assumed that it undergoes endothermic chemical changes (cracking) if used as a coolant at high temperatures.

Nobody is planning to use RP-3 in the US, so why would we go to the trouble of listing it here? There are hundreds of publications investigating RP-3, but only a few of those are listed here. This is done for a reason similar to the argument why we included Russian kerosenes in our review. Although we may never see any RP-3 in our laboratory, the techniques used in other countries to characterize and improve hydrocarbon fuels may also be applicable to our grades of RP and JP. It would be interesting to compare the properties of RP-3 with US kerosenes such as JP-4, JP-5, and JP-8 in side-by-side tests. There may be some commonalities.

## 5.1 Physical Properties of RP-3

It appears that most of the recently published reports on the physical properties of RP-3 deal only with the fuel in the near-critical or super-critical state and accurate properties at room temperature and over the entire normal liquid range are difficult to find.

### 5.1.1 Density of RP-3

The density of RP-3 at sub- and super-critical conditions at 295 to 796 K under pressures from 0.1 to 5 MPa was measured using a dynamic density measurement method that was based on mass conservation equation and that can be applied to the density measurement of single-phase flow including supercritical fluids [228]. As shown in Figure 28, the density drops abruptly as the temperature approaches the critical temperature. The uncertainty of the measurement was within  $\pm 0.635\%$  according to error analysis. The results were fitted as polynomials to analyze deviations. For the 265 experimental data points, the AAD and the maximum absolute deviation (MAD) were 0.539 and 3.29% respectively. In addition, the isobaric thermal expansion coefficient  $\alpha_P$  was derived from the fitted values of the density.

**Figure 28:** Density variations of RP-3 versus temperature under different pressures. (Reprinted and adapted from [228], with permission of ©2011 American Chemical Society; permission conveyed through RightsLink.)

It appears that a developmental fuel called Endothermic Hydrocarbon Fuel-Tianjin University (EHF-TU) is a narrow cut of distillates taken from RP-3, consisting mainly of naphthenic hydrocarbons (51.3%), alkanes (48.2%), and aromatic hydrocarbons (0.5%) with a boiling range of 455–528 K. A list of constituents showed 21 hydrocarbons (0.3 to 22 mass-%). The main constituent was *n*-dodecane. The density of EHF-TU has been measured at temperatures of 303 to 765 K and pressures of 3 to 7 MPa [229], varied from 759 to 134 kg/m<sup>3</sup>, and is similar to that of RP-3. The critical pressure of EHF-TU is about 1.913 MPa, which is below that of RP-3.

### 5.1.2 Viscosity of RP-3

The viscosity of RP-3 under critical and supercritical conditions over a temperature range of 298 to 788 K under pressures from 2.33 to 5 MPa was measured by expanding the classical capillary viscosity measurement method, and it can be applied to the viscosity measurement of single-phase flow, including supercritical fluids [230]. In these experiments, the total pressure drops of long and short measurement tubes were measured simultaneously. The uncertainty of the measurement was within  $\pm (2.1 \text{ to } 6.4)\%$  ( $k = 2$ ) according to error analysis. The results were fitted as polynomials to analyze deviations. Out of 219 points, 205 points were within the  $\pm 5\%$  error band, which is 93%. Figure 29 shows the dynamic viscosity variations of RP-3 versus temperature under different pressure conditions. Like other pure fluids, the dynamic viscosity of RP-3 increased with an increase in pressure, especially in critical and pseudocritical regions. Before reaching critical and pseudocritical points, the viscosity of RP-3 exhibited liquid-like properties where the viscosities of RP-3 decreased with an increase in temperature.

Two different methods were proposed for hydrocarbons online viscosity measurements at high temperatures and high pressures in a two-capillary viscometer based on the Hagen–Poiseuille theory [231]. The first method, called Referenced Flow Method, measures the pressure drop, mass flux and density ratios of the test and reference fluid in a two-capillary system, and then calculates the test viscosity from the ratio relations regardless of the tube parameters. In the second method, a thermal expansion method (TEM), the fluid viscosity is obtained in a two-capillary process by measuring the pressure drop ratio, density ratio, and thermal expansion of a capillary tube, such that mass flux and reference fluid are no longer required in TEM. Pure *n*-dodecane and a binary mixture of *n*-heptane and *n*-octane were selected to validate the reliability and accuracy of the two methods. Viscosities of two endothermic fuels were obtained using the two-capillary viscometer at temperatures from 303 to 673 K and pressures up to 5.00 MPa. Based on these data, a viscosity relation formula as a function of temperature for two fuels was developed within 4.2% deviation.

### 5.1.3 Thermal Conductivity of RP-3

The thermal conductivity of a representative endothermic hydrocarbon aviation kerosene fuel RP-3 was measured using the classical transient hot-wire method at sub- and supercritical pressures [232]. The measured data cover a temperature range of 285 to 513 K and a pressure range of 0.1 to 5 MPa (Figure 30). The expanded uncertainty of the experiment was less than 3.0% based on an uncertainty analysis. The measured data were correlated using a polynomial equation to analyze the deviations; 97.6% of the measured data were within a 2% error band. The AAD and MAD of the fitted thermal-conductivity data were 0.209 and 2.31% for all values respectively.

### 5.1.4 Heat-Transfer Coefficient of RP-3

The convective heat-transfer characteristics of China RP-3 kerosene under supercritical pressure conditions were studied using the finite volume method and a two-equation turbulence model with enhanced wall treatment [233]. The heat transfer with different constant wall heat fluxes was analyzed, and a correlation of heat-transfer enhancement was obtained. The effect of mass flow rate on the convective heat transfer with a varying wall heat flux condition at the supercritical pressure was investigated. Because of the special thermophysical properties of the

**Figure 30:** Variations of the thermal conductivity of RP-3 with temperature at different pressures. (Reprinted and modified from [232], with permission by ©2015 Springer Nature; permission conveyed through Copyright Clearance Center Inc.)

kerosene at supercritical pressure, the Nusselt number can only be related to the Reynolds number after the heat transfer is enhanced. The simulation results were compared with empirical formulas in the literature.

The heat-transfer characteristics of RP-3 flowing through vertically downward capillary tubes (ID=1.8 mm) were experimentally investigated at supercritical pressure ( $P=5$  MPa,  $P_R=2.15$ ) at 373 to 800 K [234]. Test results indicated that in the initial heating region, wall temperatures increased dramatically from the initial heating point and then decreased rapidly at higher heat flux, but this phenomenon diminished when the inlet Reynolds number reached 10000. In addition, heat transfer deterioration occurred when the thermal acceleration parameter ( $K_v$ ) was less than  $1.5 \times 10^{-8}$  or the buoyancy factor ( $Bo^*$ ) was less than  $1.6 \times 10^{-10}$ . A new heat transfer correlation was developed based on the experimental data and that predicted the heat transfer for RP-3 with reasonable accuracy.

A surrogate fuel composed of 53% (mol-%) *n*-undecane, 18% 1-butylcyclohexane, and 29% 1,3,5-trimethyl-benzene was proposed to simulate a specific composition of aviation kerosene RP-3, based on the method of averaging molecular weight [235]. Taking advantage of the principle of extended corresponding states and fundamental thermodynamic relationships, thermophysical and transport properties of the surrogate fuel were calculated and verified by comparison with RP-3 experimental data. A numerical study was conducted aimed at RP-3 flow heat-transfer characteristics in a vertical tube, which revealed the typical heat exchange characteristics of RP-3 flow heat exchange at supercritical pressure, and which showed that heat transfer was sig-

nificantly enhanced owing to abrupt changes of physical property when the fluid temperature approached the pseudo-critical temperature. The effect of buoyancy and turbulent kinetic energy on heat transfer needed to be analyzed.

A 2D axisymmetric numerical study of supercritical heat transfer of RP-3 flowing inside the cooling channels of scramjet used a ten-species surrogate fuel to evaluate the viscosity of RP-3 at 3 MPa with NIST Supertrapp software [236]. Density, viscosity, heat capacity, and thermal conductivity at 300–800 K and 3 MPa were available in the literature from experimental data and shown in four graphs. In addition, viscosity was computed from a commercial code with a ten-species surrogate. A study of the effects of heat flux, mass flow rate, and inlet temperature on supercritical heat-transfer processes indicated that when the wall temperature rose above the pseudocritical temperature of RP-3, the heat-transfer coefficient decreased as a result of a drastic decrease in the specific heat. The conventional heat-transfer correlations were no longer appropriate for the supercritical heat transfer of RP-3. Other formulas, which were proposed for supercritical CO<sub>2</sub> and water, gave a good prediction except when the wall temperature was near or higher than the pseudocritical temperature.

The flow patterns of two-phase flow inside the cooling channels of a scramjet have a great influence on the heat-transfer characteristics. Phase transition processes of RP-3 kerosene flowing inside a square quartz-glass tube were experimentally investigated [237]. Three distinct phase transition phenomena (liquid-gas two-phase flow under sub-critical pressures, critical opalescence under critical pressure, and corrugation under supercritical pressures) were identified. The conventional flow patterns of liquid–gas two phase flow, namely bubble flow, slug flow, churn flow, and annular flow, were observed under sub-critical pressures. Dense bubble flow and dispersed flow were observed when the pressure was increased toward the critical pressure whereas slug flow, churn flow, and annular flow disappeared. Under critical pressure conditions, the opalescence phenomenon was observed. Under supercritical pressures, no conventional phase transition characteristics, such as bubbles, could be seen. However, some kind of corrugation appeared when RP-3 transferred from liquid to supercritical conditions. The refraction index variation caused by a sharp density gradient near the critical temperature is thought to be responsible for this corrugation.

Two-dimensional coupled heat transfer of RP-3 in a tube was modeled and computed [238]. Effects of thermal conductivity on coupled heat transfer and influences of radial property variation, buoyancy, and acceleration on heat-transfer deterioration were investigated. Results indicated that solid thermal conductivity had almost no effect on the convective heat transfer, but high wall metal thermal conductivity reduced radial temperature gradients inside the wall. Acceleration effect on heat transfer could be neglected under the typical operating conditions of scramjet engines. Buoyancy caused heat-transfer deterioration for upward flow at relatively small values of the specific mass flow rate. When the value of the specific mass flow rate was relatively large, radial property variation caused heat-transfer deterioration. Heat-transfer de-

terioration appeared when the ratio of heat flux to specific mass flow rate was larger than  $410 \text{ J/kg}$  at  $4.5 \text{ MPa}$ .

A three-dimensional Navier–Stokes code was used to investigate the heat-transfer characteristics and flow resistance of kerosene RP-3 under supercritical pressure in a tube [239]. For the numerical simulation, the thermophysical and transport properties of a surrogate fuel, which consisted of 53% (mol-%) *n*-undecane, 18% 1-butylcyclohexane, and 29% 1,3,5-trimethyl-benzene, were calculated and verified by comparison with RP-3 experimental data. The length and diameter of the stainless tube were 300 and 1.8 mm respectively. The inlet temperatures varied from 370 to 770 K, and the operating pressures were 3, 4 and 5 MPa. The mass flows were 2, 3 and 4 g/s, with different heat-flow densities of 300, 400, 500, and  $550 \text{ kW/m}^2$ . The research results showed that the calculated pressure drops agreed well with the experimental data when the temperature was lower than 720 K. The discrepancy between numerical and experimental data became gradually more distinct after the temperature rose to higher than 720 K. When the bulk temperature was lower than the critical temperature, the pressure drops under different operating pressures were almost the same. Although the bulk temperature was higher than the critical temperature, the diversion of pressure drop under different operating pressures became gradually more noticeable. The local Nusselt number first increased and then suddenly decreased at a certain position. The heat-transfer deterioration was caused by intensive variations of thermo-physical properties of the fuel under supercritical pressures. The sudden decrease shift appeared earlier when the heat flux was larger.

An updated correlation for heat transfer to RP-3 in vertical tubes under supercritical pressure was based on the literature database of RP-3, which contained 1722 experimental data points compiled from six published papers [240]. It had a MAD of 11.0%, predicting 83.7% of the entire database within  $\pm 20\%$ , whereas the best existing model available in the literature prior to that time only had an MAD of 24.1%, predicting 58.4% of the entire database within  $\pm 20\%$ . The new model improved the prediction accuracy of RP-3 heat transfer under supercritical pressure remarkably.

The mixed convection heat transfer to supercritical RP-3 in vertical tubes and the effects of buoyancy and thermophysical properties on convection were investigated [241]. The wall heat fluxes ( $200\text{--}500 \text{ kW/m}^2$ ), inlet pressures (3–5 MPa) and inlet Reynolds numbers (5000–10500) were maintained constant in the experiments. The study showed that heat-transfer impairment occurred in the inlet region for all upward flow conditions due to buoyancy effects, which was not observed in the downward flow tests. The heat-transfer coefficient increased as the fluid bulk temperature increased as a result of comprehensive effects of thermophysical properties. At a lower inlet Reynolds number (5700), the radial velocity profile changed in downward flow conditions leading to heat-transfer enhancement due to buoyancy effects. The buoyancy effects were also significant for higher inlet Reynolds numbers (10500).

The heat transfer to supercritical pressure RP-3 in vertical miniature round tubes and the influence of heat flux, fluid inlet temperature, flow orientation and pressures on the heat transfer of RP-3 were measured [242]. The heat transfer of supercritical pressure kerosene RP-3 flowing through a vertical pipe with an inner diameter of 1.8 mm was investigated for inlet pressures of 3–5 MPa, which is beyond the critical pressure (2.33 MPa), and an inlet Reynolds number of 5000. Heat-transfer deterioration occurred only for upward flow at the entrance section owing to wall shear forces weakened by buoyancy forces. In heated downward flow, heat transfer was enhanced with high buoyancy effects. In contrast, heat transfer in heated upward flow increased monotonically with increasing buoyancy. The existing criteria for evaluating the buoyancy effects are invalid for supercritical hydrocarbon fuel. Periodic thermoacoustic oscillation (0.125–0.25 Hz) was detected in the case of low inlet temperatures under high heat flux. Probably, some micro bubbles may be generated near the tube wall under high undercooling condition. Owing to the high solubility of supercritical pressure fluids, these micro bubbles rapidly vanish into the mainstream, resulting in a sharp local fluid bulk temperature decrease.

Heat transfer to RP-3 at supercritical pressures in vertical capillary tubes with inner diameters of 0.538, 1.09, and 1.82 mm under heating conditions and the effects of system pressure, heat flux, mass flow rate, and flow direction were experimented with and analyzed for a wide range of supercritical conditions [243]. The effect of capillary tube inner diameter on heat transfer was compared at otherwise identical conditions. The results indicated that sharp variations of thermal properties with temperature were the key factor in influencing heat transfer. Normal, deterioration, and enhancement heat-transfer phenomena generally occurred along the  $X/L$  dimensionless position along the tube. Nusselt number variation showed good agreement as long as the temperature ratio  $T_b/T_{pc}$  was lower than 0.80 and  $Bo^* = 1.0 \times 10^{-8}$  would be the critical point for evaluating buoyancy influence. Two empirical correlations of Nusselt numbers were proposed for downward and upward flow heat transfer in 1.09-mm tubes.

Convective heat-transfer characteristics of RP-3 at supercritical pressures flowing through U-shaped tubes with an inner diameter of 1.82 mm and bending radius of 20, 30, and 40 mm were experimentally investigated [244]. Inner wall temperature and heat-transfer coefficient variations were analyzed under different conditions including heat flux, system pressure, tube bending radius, and flow direction. Test results indicated that centrifugal force strengthens the flow mixing at the bending section and the heat-transfer coefficient was enhanced to 140 to 200% compared with a straight tube. Heat-transfer coefficient values increased with a decrease in bend diameter.

Experimental investigations into heat transfer of RP-3 at supercritical pressure in a horizontal capillary round tube examined the influence of buoyancy on heat transfer of RP-3 [245]. Buoyancy-induced deviations are significant in horizontal flows, and may lead to non-uniform temperature distributions in cross sections of the test section even for narrow round tubes. The buoyancy effects of heat transfer can be evaluated

by the ratio of the Grashof numbers, the non-dimensional parameter  $Gr_q/Gr_{th}$  developed by Petukhov [246]. This criterion was tested for the horizontal flow in narrow round tubes under supercritical pressure conditions, leading to a correlation of Nusselt numbers for supercritical pressure fuels in horizontal tubes.

Convective heat-transfer characteristics of RP-3 at supercritical pressure ( $P = 5$  MPa) in vertical helical tubes were experimentally studied [247]. The helical tube had an inner diameter of 1.82 mm, a helical diameter of 20 mm, and pitch of 10 mm. Circumferential temperatures were measured during both upward and downward flow experiments and the results indicated that:

1. The secondary flow induced by centrifugal force moves outward of the cross section and the inside temperature was larger than the outside temperature. The outside heat-transfer coefficient was about 31% larger than the inside heat-transfer coefficient.
2. Heat-transfer enhancement leading by centrifugal secondary flow was the key factor when the Richardson ratio was larger than 10.
3. Two correlations of Nusselt numbers were developed to predict heat transfer of RP-3 in helical tubes based on experimental data at supercritical pressure.

A CFD model was applied to study flow dynamics and heat transfer of the aviation kerosene RP-3 in a horizontal square cooling channel under asymmetric heating and buoyancy effects at various supercritical pressures [248]. The turbulent fluid flows were described by the standard  $k-\varepsilon$  turbulence model with an enhanced wall treatment, and the strong thermophysical property variations were calculated using the extended corresponding state approaches and a four-component surrogate model of RP-3. The effects of secondary flows and heat flux redistribution induced by buoyancy on supercritical-pressure heat transfer were analyzed. Results indicated that drastic variations of the fuel density with temperature at a supercritical pressure of 3 MPa induced a strong buoyancy effect on heat transfer. As the operating pressure increased from 3 to 5 MPa, the density variation of RP-3 decreased, consequently leading to a weakened buoyancy effect.

Thermo-acoustic instability accompanied by abnormal sounds was observed for supercritical RP-3 flowing in a heated small-scale channel [249]. The instability appeared when the applied heating power exceeded a threshold value. The threshold power can be affected by three operating parameters: fuel mass flow rate, channel inlet temperature, and channel operating pressure. A series of experiments were designed to study the effect of these three parameters on the threshold power. It was found that the threshold power changed monotonously with fuel mass flow rate, whereas there was no simple linear effect of inlet temperature and operating pressure on the threshold power. Two dimensionless parameters, namely, sub-pseudo-critical number and true trans-pseudo-critical number were used to study the boundary of the thermo-acoustic instability. The result revealed that the system stability was significantly enhanced by increasing operating pressure, whereas the effect

of mass flow rate on the system stability was strongly coupled with inlet fluid temperature. The heat transfer was obviously enhanced when thermo-acoustic instability occurred. To understand the relationship between the enhancement on heat transfer and thermo-acoustic instability, the characteristics of thermo-acoustic instability were further investigated [250]. The pressure drop fluctuations were used to represent the characteristics of thermo-acoustic instability. Two main characteristics of thermo-acoustic instability are amplitude and phase duration of the pressure oscillations. These characteristics could be affected by three operating parameters: fuel mass flow rate, channel inlet temperature, and channel operating pressure. A series of experiments were designed to study the effect of these three parameters on the characteristics. It was found that the amplitude increased with increasing mass flow rate, whereas the duration reached the maximum value when mass flow rate was a certain value; the effects of operating pressure on the characteristics of thermo-acoustic instability were strongly dependent on the threshold power.

During experimental investigations into the flow and heat-transfer instabilities of RP-3 under supercritical pressures in a vertical tube with an inner diameter of 2 mm, the flow changed from laminar to the transition regime as the fuel was heated, which resulted from a decrease in fluid density and increase in velocity [251]. A 13-component surrogate model of RP-3 was used to calculate the thermophysical properties of fuel. Under large wall heat flux conditions, instabilities in flow and heat transfer are observed when the inner wall temperature and outlet fluid temperature approached the pseudo-critical temperature respectively. The former was accompanied by enhancement in heat transfer and could be explained by the pseudo-boiling mechanisms. Thermally induced pressure oscillations due to drastic density variation was found to be the reason for the latter case. During a study of the effects of inlet pressure, wall heat flux, and inlet Reynolds number on flow and heat-transfer instabilities, it was found that higher inlet pressures and heat fluxes can weaken the flow instabilities. The influence of inlet Reynolds number was more complicated. Different types of flow instabilities could be observed with the increase in inlet Reynolds number.

#### 5.1.5 Thermodynamic Properties of RP-3

The isobaric specific heat capacity of RP-3 was measured using a vacuum flow-calorimeter in the near-critical and supercritical regions [252]. During these experiments, the temperature was changed from 292 to 824 K, and the operation pressure was changed from 2.40 to 5.98 MPa. The operating pressure, fuel inlet and outlet bulk temperatures, mass flow rate, and heat power were measured using a pressure gauge transducer, K-type sheathed thermocouples, a Coriolis force flow meter, and current and voltage meters respectively. The estimated uncertainty of the measurement was lower than 2.1%. The expanded accuracy of the measured method for the low-temperature region was verified by comparing with water at a pressure of 3 MPa;

the high-temperature region was verified by comparing the temperatures calculated from  $C_p$  integrating enthalpy with the temperatures measured in the experiments.

The isobaric specific heat capacity of RP-3 at high temperature and high pressure was measured with a flow calorimeter [253]. Based on the energy conservation principle, the formula for heat capacity was derived and its measurement was performed by the convective mixing method between the hot and cold fuel. Taking the precision of the instrument and the error transfer into account, the relative expanded uncertainty of this method was about  $\pm 6.38\%$  (coverage factor  $k = 2$ ). Meanwhile, the accuracy and reliability were verified by comparing with the well-known data for water and *n*-decane. Within the temperature range 296–719 K and under the pressure range 2.4–4.0 MPa, the measurement for the kerosene RP-3 was carried out and the experimental observations agreed well with published data.

### 5.1.6 Critical Point Properties of RP-3

A short residence time flow equipment for the measurement of the critical temperature and pressure of fluids was developed to determine the critical properties of endothermic hydrocarbon fuels [254]. The short residence time (about 10 to 50 s) at an elevated temperature minimized the decomposition and other reactions of fuels. Taking *n*-pentane, *n*-hexane, and cyclohexane as standard reagents, the reliability of the apparatus was checked. The critical properties of endothermic hydrocarbon fuels Simulated JP-7 and RP-3 were determined. Four estimation methods based on the volume average boiling point and relative density were also used to estimate the critical properties of these fuels. The comparisons between the experimental and predicted values indicated that the correlations suggested by the API and Riazi Daubert were reliable for predicting the critical properties of fuels.

The critical pressure and temperature of RP-3 were determined by flow visualization [255]. The flow pattern images of RP-3 at different pressures and temperatures were recorded and the critical pressure was identified by disappearance of the phase boundary, whereas the critical temperature was determined by appearance of the opalescence phenomenon under the critical pressure. The opalescence phenomenon is unique to the critical point. The critical pressure and temperature of RP-3 were determined to be 2.3 MPa and 646 K respectively. The density of RP-3 at the critical point was identified as  $221.18 \text{ kg/m}^3$  [228].

## 5.2 Chemical Properties of RP-3

### 5.2.1 Composition of RP-3

RP-3 consists of 52.44% alkanes, 7.64% alkenes, 18.53% benzenes, 15.54% cycloalkanes, 4.39% naphthalene, and 1.46% other hydrocarbons. A more detailed analysis

showed 45 different hydrocarbons ranging all the way from *n*-hexane to 2-methylnaphthalene [223].

### 5.2.2 Thermal Stability of RP-3

#### 5.2.2.1 Coke Deposition in Stressed RP-3

Solid depositions from thermal stressing of an RP-3 jet fuel model compound, *n*-dodecane, was studied in the presence of three initiator additives, 1-nitropropane, triethylamine, or 3,6,9-triethyl-3,6,9-trimethyl-1,4,7-triperoxonane, to show the role of initiators in the carbon deposition by thermal cracking of jet fuels [256]. It was found that the thermal cracking rate of *n*-dodecane is enhanced by the initiators in the following order: 3,6,9-triethyl-3,6,9-trimethyl-1,4,7-triperoxonane > 1-nitropropane > triethylamine, and that 3,6,9-triethyl-3,6,9-trimethyl-1,4,7-triperoxonane and triethylamine remarkably inhibit the formation of pyrolytic deposit by 30–50% at a similar conversion level. Temperature-programmed oxidation of deposits indicated that reactive deposition is improved slightly by 3,6,9-triethyl-3,6,9-trimethyl-1,4,7-triperoxonane and triethylamine, but the less reactive deposits were reduced because of possible radical scavenging or the hydrogen donation effect, resulting from the decomposition of 3,6,9-triethyl-3,6,9-trimethyl-1,4,7-triperoxonane and triethylamine. Scanning electron microscopy showed that triethylamine and 1-nitropropane also have a significant effect on the deposit morphologies. Those results were also observed in the thermal stressing of Chinese RP-3 jet fuel with initiators.

Flowing RP-3 was stressed to 5 MPa and heated up to 700 K (427 °C) in a stainless steel 1Cr18Ni9Ti tube (inner diameter 1.8 mm, outer diameter 2.2 mm) with constant heat flux [257]. The inlet temperature was controlled at 353, 373, 400, and 423 K (80, 100, 127, and 150 °C). The amount of surface coke deposition was weighed. The results showed that, as RP-3 inlet temperature increased, coke deposition peaks shifted upstream and grew slightly. The total amount of coke deposition increased initially and then remained at a certain value after inlet temperature reached 400 K (127 °C).

The influence of pressure on the surface coke deposition of RP-3 was studied by experiments where the flowing RP-3 was heated up to supercritical state in a single-pass stainless steel tube measuring 2 m long (inner diameter 2.2 × 0.2 mm wall thickness, 1Cr18Ni9Ti alloy) with constant heat flux and mass flow of 4 g/s [258]. The amount of surface coke deposition was obtained by a weighting method. The influences of pressure on RP-3 surface coke deposition rate were investigated by changing the pressure. The result showed that high pressure can suppress coke deposition to a certain extent. The location of the coking peak value tended to move backward along the experimental segment with increased pressure, but the shapes of surface coke deposition distribution curves under different pressures were the same.

The effect of surface coke deposition on the heat transfer of RP-3 under supercritical pressure was studied by flowing RP-3 kerosene at 5 MPa, and heated up to 403 to 623 K (130 to 450 °C) in a stainless tube (inner diameter 1.8 mm, outer diameter

2.2 mm, 1Cr18Ni9Ti) with a constant heat flux and a mass flow rate of 3 g/s [259]. The working fluids flowed downward through a tube measuring 1800 mm long. The experimental results indicated that insoluble products deposited onto a metal surface have a significant impact on flow resistance and heat transfer. The effect of coke deposition on the heat-transfer coefficient can be divided into four regimes: a) onset heat-transfer enhancement zone; b) transition zone; c) heat-transfer impairment zone; d) heat-transfer stabilizing zone.

An improved methodology was proposed to experimentally obtain detailed information on the local composition and temperature along the microchannels of a heat exchanger in an electrically heated capillary tube (inner diameter 1 mm) [260]. This method used a variable reactor tube length to carry out thermal cracking of supercritical hydrocarbon aviation fuels while the electric current heating was maintained constant. A series of experimental data on detailed local chemical compositions of cracked hydrocarbon fuel along the cooling microchannels were reported under supercritical conditions (5 MPa, 953–973 K, 680–700 °C), and the calculated thermodynamic properties, flow velocity, and residence times along the tube were reported. A modified molecular reaction model consisting of 18 species and 24 reactions was developed to predict thermal cracking of hydrocarbon aviation fuels within a wide range of cracking conversion fractions (up to 86%) and compared with experimental results.

A series of electrically heated circular tube experiments were conducted to investigate the influences of physical factors on supercritical RP-3 thermal oxidation coking [261]. The flowing RP-3 kerosene was stressed from 3 to 7 MPa and heated to different bulk temperatures below 723 K (450 °C) in a stainless steel tube (inner diameter 1.8 mm and outer diameter 2.2 mm, 1Cr18Ni9Ti) with various heat fluxes. Tube surface coke deposits and liquid-space coke were both collected and weighed using different methods to evaluate the coking characteristics. Some test tube coke compositions were analyzed for the investigation of chemical reactions. The experimental results showed that the fuel temperature is a generated dominant influence factor for RP-3 coking, and its influence is greater than that of the wall temperature. The system pressure had no obvious effect for RP-3 with a high distillation range ( $C_9$ – $C_{12}$ ). The wall coke deposit quantity gradually increased with the mass velocity. The average coking rate was proportional to  $Re_{in}$ . The inlet temperature had little effect on the liquid-space coking, and the coke particles basically posed no threat to the fuel path and nozzle.

Kerosene RP-3 was pyrolyzed in an electrically heated horizontal channel with an internal diameter of 4.0 mm at temperatures up to 913 K (640 °C) and at a pressure of 3 MPa [262]. The dynamic behavior of the coking process due to fuel pyrolysis was experimentally investigated. The coke deposition process was considered to be the net result of two simultaneous sub-processes: a deposition process and a removal process. Results indicated that coking was an unsteady and dynamic process with randomness. During the entire duration of coking runs, the pressure drop across the test channel and the fuel outlet temperature oscillated somewhat. The wall temperature and the

pressure drop variation within a wide range became unpredictable, owing to the random coke build-up and removal in a short time. However, repeated experiments were carried out to get reliable results of some regular patterns of coking. The pressure drop exponentially increased and the wall temperature rapidly changed at the initial stage of a coking run. The pressure drop increased linearly, but the wall temperature nearly achieved steady state at the following stages. Surprisingly, and opposite to the general assumption that coke is a thermal resistance layer that reduces heat transfer, surface deposition enhanced the heat transfer during pyrolysis of RP-3 under the given test conditions.

A numerical simulation of the pressure effect on thermal cracking of RP-3 under supercritical conditions has been conducted based on a complete set of conservation equations [263]. A four-species surrogate for RP-3 was selected to calculate the thermophysical properties. The modified Kumar–Kunzru chemical kinetics model consisting of one primary reaction and 23 secondary reactions was adopted to simulate the cracking process. Detailed variations of the thermophysical property, thermal cracking behavior, and flow and heat-transfer processes of the fuel were investigated. Simulation results indicated that the conversion of RP-3 is proportional to the pressure. Increasing pressure would enhance the heat transfer when the fuel temperature is below 830 K, and a reversed trend was observed as the fuel temperature further increased. The heat transfer is reduced when the fuel temperature approaches a critical value if the pressure is lower than 7 MPa.

A mathematical model was developed for studying fluid dynamics and heat-transfer characteristics of RP-3 at supercritical pressures [264]. The model accommodated a detailed pyrolytic chemical reaction mechanism, which consisted of 18 species and 24 elementary reactions similar to [260]. Accurate calculations of thermophysical properties at supercritical pressures were incorporated. After rigorous model validations, numerical studies of turbulent heat transfer of RP-3 in a micro cooling tube at a supercritical pressure of 5 MPa were conducted under operating conditions of both constant wall heat flux and constant surface temperature to obtain a fundamental understanding of the complex physicochemical processes. Results indicated that endothermic fuel pyrolysis, which prevails once the bulk fluid temperature rises above 750 K, dictates the fluid flow and heat-transfer process in the high fluid temperature region. Significant variations of the fluid thermophysical properties have strong impacts on other processes. Two scenarios of heat-transfer enhancement resulting from property variations under the tested conditions were analyzed.

Surface coke deposition mechanisms of supercritical RP-3 were studied under stable and pressure oscillation heat-transfer conditions [265]. The flowing RP-3 kerosene was pressurized to 5 MPa and heated from 400 to 723 K in a stainless tube (inner diameter 1.8 mm; outer diameter 2.2 mm; length 1800 mm) with a constant heat flux. The experimental downward mass flow rate was fixed at 3 g/s ( $1180 \text{ kg m}^{-2} \text{ s}^{-1}$ ). Constricted flow experiments were performed with 1-h duration with a stable flow, 1 h with 600 Hz

induced vibration, and long duration with 566 Hz vibration. The two vibration frequencies were close to the main frequencies of combustion chamber pressure oscillation under actual working conditions. Flow resistance, heat-transfer characteristics, coking amount, and component analysis were compared between stable and vibration conditions. The results indicated that vibration can affect the coking distribution to become much more uniform and extend the tube working time. Vibration inhibited the exponential growth of flow resistance by changing coke formation compared with the stable condition. Three obvious regions for heat transfer were considered during the long-duration vibration experiments. For coking element analysis, trace amounts of Cu have catalytic effects under vibration conditions.

The thermal oxidation deposition characteristics of RP-3 have been experimentally studied in a vertical tube at supercritical pressure [266]. Thermal stressing of the fuel was carried out in a heated tube made from stainless steel 321 (SS321, 1Cr18Ni9Ti), as-received, pre-oxidized, and electrolytically passivated for 1 h. All of the experiments were conducted under a constant pressure of 5 MPa, at fixed inlet and outlet fuel temperatures of 400 and 723 K respectively, and under the same heat flux and mass flow rate conditions. Deposition of coke on the different segments of the tube was analyzed using a weighing method to quantify the deposition profile along the length of the test section. The morphology and components of the surface deposition were examined along each tube, with different surface treatments, to investigate the surface thermal deposit mechanisms. It was found that the pre-oxidized and electrolytically passivated treatments could reduce the total coke deposition by about 35.83 and 58.33% respectively, as a result of the formed passivation layer and reduced surface roughness in the treated progress in contrast to the as-received CRES-321 tube. On the basis of SEM images and component analysis of the surface deposit, the deposit on the treated tube surface could be attributed to the adhered deposit formed in the liquid fuel rather than the surface catalytic filamentous deposition on the untreated tubes.

Controllable hydrocarbon cracking with greatly reduced coke deposits has been realized by the addition of a little ethanol over a bifunctional coating [267]. The coating, consisting of perovskite and phosphotungstic acid, was prepared in a nickel-based super alloy tube reactor (inner diameter 3 mm  $\times$  width 0.5 mm  $\times$  length 1000 mm) by the wash-coating method. SEM, EDS, and X-ray diffraction were used to characterize the morphology and phase composition of the coating and deposited cokes. The results showed that  $\text{BaWO}_4$ ,  $\text{BaCeO}_3$ ,  $\text{SiO}_2$ , and  $\text{H}_3\text{PW}_{12}\text{O}_{40}$  coexisted of the 4.2  $\mu\text{m}$  thick coating with a uniform distribution. The anti-coking tests were conducted during the supercritical thermal cracking of RP-3 with a flow rate of 1 g/s for 30 min at 973 K (700  $^\circ\text{C}$ ) and 4 MPa. The results showed that the efficiency of coke inhibition reached up to 96%, and the durability (i.e., pressure drop of tube reactor and cooler) of the system was improved. The deposited cokes were characterized by temperature-programmed oxidation and using SEM. The pyrolysis products, including gas and liquid, were analyzed. The results indicated that the strategy based on ethanol and a bifunctional coating not only can eliminate the coke deposits on the reactor tube

walls but can also reduce the amount of typical coke precursors related to the aromatic condensation cokes. A possible mechanism for the process has been proposed. In general, phosphotungstic acid in the coating is capable of catalyzing the dehydration of ethanol for the production of water. The perovskite structures can remove coke deposits on the coating through carbon-steam gasification reaction.

In order to study the mechanism of thermal decomposition coking of RP-3 at a supercritical pressure of 5 MPa in helical tubes, the bulk temperature of the fuel was varied from 400 to 723 K, and the mass flux was varied from  $393 \text{ kg m}^{-2} \text{ s}^{-1}$  to  $1178 \text{ kg m}^{-2} \text{ s}^{-1}$  [268]. Four types of helical tubes with different helical diameters were bent and tested for a maximum duration of 5 h. The total coking amount and distribution were analyzed using a weighing method. The results indicated that coking distribution in a coiled tube was more uniform than in the case of a straight tube, and that there was no prominent local coking peak because of the effect of centrifugal forces. The maximum total coking amount among all the experiments decreased by approximately 69.5% compared with that in a straight tube. Three main types of coking morphologies were observed under the SEM: thin coking layers, dense clumps, and crystalline particles.

#### 5.2.2.2 Effect of Additives on Cracking of RP-3 Fuel

Solid coke deposits from thermal stressing of a jet fuel model compound, *n*-dodecane, was studied in the presence of three initiator additives, 1-nitropropane (NP), triethylamine (TEA) or 3,6,9-triethyl-3,6,9-trimethyl-1,4,7-triperoxonane (TEMPO), to show the role of initiators in the carbon deposition during the thermal cracking of jet fuels [256]. It was found that the thermal cracking rate of *n*-dodecane was enhanced by the initiators in the following order: TEMPO > NP > TEA and that TEMPO and TEA remarkably inhibited the formation of pyrolytic deposits by 30–50% at a similar conversion level. Temperature-programmed oxidation of deposits indicated that reactive deposition can be reduced slightly by TEMPO and TEA, but the less reactive deposits are reduced because of possible radical scavenging or the hydrogen donation effect, resulting from the decomposition of TEMPO and TEA. SEM showed that TEA and NP also have a significant effect on the deposit morphologies. Those same results were also observed in the thermal stressing of Chinese RP-3 fuel with initiators.

Various additives were tested in the hope that they would prevent the formation of carbonaceous deposits during thermal stressing of hydrocarbons at high temperatures ( $> 773 \text{ K} = > 500^\circ \text{C}$ ) [269]. Three hydrogen donors, tetralin (THN),  $\alpha$ -tetralone (THNone), and benzyl alcohol (BzOH), as well as two organic selenides, diphenyl selenide ( $\text{Ph}_2\text{Se}$ ) and diphenyl diselenide ( $\text{Ph}_2\text{Se}_2$ ), in addition to their mixtures, were selected as thermally stable additives to inhibit the deposition from the thermal stressing of *n*-dodecane and Chinese RP-3 (No. 3 jet fuel). It was found that the amount of solid deposits from thermal stressing of RP-3 was reduced by 77.0% with the additive of  $\text{Ph}_2\text{Se}_2/\text{THN}/\text{THNone}$ . It was found that hydrogen donor THN/THNone and organic selenides possibly reduce the carbon deposits through retarding the thermal crack-

ing rate, blocking surface catalysis, and depressing the reactivity of sulfur with the surface metals, as well as their synergistic effect. The morphologies of deposits also dramatically changed after adding organic selenides or hydrogen donors.

### 5.2.2.3 Catalytic Cracking of RP-3 Fuel

Catalytic cracking of Chinese RP-3 can be enhanced by Cu/ZSM-5 (CZ) zeolite and Pt/CeO<sub>2</sub>/Al<sub>2</sub>O<sub>3</sub> (PCA) composite catalysts [270]. The PCA, PCA + CZ, and CZ catalysts had been prepared using an impregnation method. It was found that PCA + CZ had better catalytic cracking activities than the other catalysts, but they had poor stabilities at high temperatures. The addition of CZ onto PCA to form a composite catalyst may be an effective approach to maintaining both catalytic activity and thermal stability (>923 K = >650 °C).

Catalytic cracking of RP-3 over wall-coated Pt/ZrO<sub>2</sub>-TiO<sub>2</sub>-Al<sub>2</sub>O<sub>3</sub> catalysts with different Al<sub>2</sub>O<sub>3</sub> ratios was investigated under high temperature and pressure conditions [271]. It was found that the gas yield and heat sink of catalytic cracking of RP-3 were improved compared with thermal cracking.

A series of WO<sub>3</sub>-ZrO<sub>2</sub> composite oxides were prepared by co-precipitation and their catalytic performances for RP-3 kerosene cracking were investigated [272]. The amount of gas evolution as the result of catalytic cracking over Pt/WO<sub>3</sub> (4 mass-%)-ZrO<sub>2</sub> catalyst within the temperature region 923–973 K (650–700 °C) was about 1.5 times higher than that of thermal cracking. After the composite oxides were calcined at 1073 K (800 °C) for 3 h, they almost lost their catalytic activities.

## 6 Other Foreign Grades of Kerosenes

### 6.1 Russian Grades of Kerosenes

At the beginning of the rocket age in the US, RP-1 was a low sulfur, low aromatics kerosene distillate fuel (MIL-P-25576, 1956). Parallel development efforts in the USSR in the 1950s produced a similar, slightly denser propellant later known in the US as RG-1 and known in Russia as

## НАФТИЛ

A comparative evaluation of Russian kerosene and US RP-1 was performed to support integration of Russian propulsion elements into the US space program [85]. A two-prong approach was followed to provide a better understanding of the differences. First, analysis provided insight into chemical and physical properties and the theoretical performance difference between the two fuels. Second, hot fire testing provided performance and engine operational data with the two fuels. Analysis of the

data showed three major differences: Russian kerosene was more dense than RP-1. It had a lower sulfur content, and temperature rise with Russian kerosene while passing through the cooling jacket was lower. No significant difference in the characteristic exhaust velocity was found. The data generated during this study were to be used in two major ways. First, initial assessments could be made to identify advantages and disadvantages of using Russian kerosene in US vehicles. Second, impacts of using RP-1 with Russian engines could be evaluated. A limited quantity of Russian kerosene used on the RD-180 engine was acquired from Energomash. A portable test stand approach with a small engine was a low-resource, time-effective method of getting hot-fire engine data. Work at NASA MSFC started in 1994 and was completed in 1995.

Over the years, the Russians have developed and used several forms of natural kerosenes and synthetic hydrocarbons as rocket engine fuels. As with the US, the Russians initially used kerosenes for military air-breathing applications and later used them as rocket fuels.

## 6.2 T-1

The Russian kerosene with a designation of T-1 (aka TS-1) kerosene appears to be the first version of kerosene-based hydrocarbon rocket fuel used by the Soviets immediately following WWII. The evolution of this fuel is not known, though it appears to have been used more commonly in military applications, most notably the early versions of the Scud missile and its variants. Its interchangeability with RG-1 is not known, but it was reportedly used in some Soyuz launches. It may have been a forerunner to RG-1.

## 6.3 T-6

The Russian kerosene T-6 may have been initially developed to power the Mikoyan MIG-25 jet aircraft. T-6 is a hydrogenated naphthenic kerosene that is processed to have low volatility, a low freezing point, low aromaticity, high thermal stability, and good relight capability. There is no equivalent to this fuel available in the US, although in the 1980s the USAF demonstrated the production of fuels similar to T-6. In fighter aircraft, as in any volume-limited operations, the higher density of the kerosene fuel translates into wider range. It was generally believed that this fuel, like T-1 and RG-1, was produced from the kerosene fraction of naphthenic crude oil. T-6 is also used as a substitute for RG-1 in engine tests because of its similar physical properties and increased availability. The RD-180 engines were acceptance tested in Russia using T-6 and then shipped to the US, where they were launched using RP-1 [1, 3].

## 6.4 RG-1

The type of kerosene typically used in the Russian space program, RG-1 is also known as “naphthyl” and its specification is defined in Russian state specification TU 38.001244. Like RP-1, it is a low-volatility kerosene fuel, but there are some critical differences, most notably the higher density and lower sulfur content. The higher density results from the chemical hydrocarbon types in RG-1 and T-6. The kerosene fraction of naphthenic crude oil contains 2-ringed (fused decalins) and 3-ringed paraffins, which are denser than the single-ringed paraffins. The density can be even further increased by chilling the fuel prior to loading onto the vehicle, which is a common practice that has been performed on previous (e.g., N-1, ENERGIYA) and is performed on current (e.g., SOYUZ) launch systems. Its high thermal stability and performance are supported by a high fraction of fused naphthenes (decalins). It is handled in metal containers under a humidity-controlled nitrogen gas barrier to prevent the infiltration of oxygen or water into the fuel. The freezing point for RG-1 has been reportedly specified to be less than 208 K (−85°F) in order to support launch operations in Siberia, but this has not been verified in any of the sources reviewed [273].

## 6.5 TM-185

The liquid hydrocarbon fuel TM-185 is used in several battlefield and ICBM missile systems, such as the R-12 SANDAL. It reportedly consists of 80–92% kerosene (probably T-1) diluted with gasoline. Its simplicity and ease of production has resulted in its being adopted for use in several emerging third-world missile systems (e.g., the North Korean TAEPO-DONG 2 and HWASONG 5, the Iranian SHAHAB-6). TM-185 may have been used as the fuel in both stages of the Iranian SAFIR satellite launch vehicle, although the NIAS report errs in describing AK-271/TM-185 as a hypergolic combination [274].

# Metals of the 2<sup>nd</sup> and 3<sup>rd</sup> Row and their Hydrides

## Metals of the 2<sup>nd</sup> and 3<sup>rd</sup> Row and their Hydrides

This chapter on metals of the second and third row of the periodic table of elements and their hydrides may be misplaced in an *Encyclopedia of Liquid Fuels*, because these are all solid compounds. We anticipate that such materials would be used as finely divided powders or nanometals suspended in liquid fuels.

### 1 Rare Gases (“Noble Gases”) as Rocket Propellants

For a book on the chemistry of rocket propellants, it would have been best to arrange the sequence of chapters by the sequence of elements in the periodic table of elements. Instead, for an encyclopedia, the chapters were arranged in alphabetical order. If we had arranged the chapters in the order of the periodic table of elements, as we did in the past, the next propellant to be discussed after hydrogen would have been helium; however, helium is used mostly as a pressurant for propellants and coolant for infrared optics and not as a propellant by itself. It requires a source of energy to heat it up and use it for propulsion. The energy can be supplied externally (electrothermal thrusters) or from chemical reactions in contact with helium. Helium can be used as a diluent for gaseous oxygen/hydrogen mixtures and thus allow the formation of non-detonable, non-self-propagating mixtures that can be ignited like a monopropellant over a catalyst. It has been attempted to prepare chemical compounds from “noble” gases and this attempt has been successful in the case of the rare gas fluorides and oxyfluorides of krypton through xenon, but not for helium or neon; however, no rare gas hydrides have been found.

Experimenters have demonstrated the ability to create metastable helium and store it as a Bose-Einstein condensate. The conversion of metastable helium to normal helium would enable a specific impulse of 2825 s.

A metastable version of helium (often designated as He\*) may be storable to some degree. He\* is an He atom with one electron promoted outside of its normal shell location, and in a reversed spin state. He\* atoms can be produced by running electrical current through helium gas. He\* can be produced by a helium-neon laser at better than 10% efficiency. Normally this atom is very unstable. In the presence of opposite spin He\* (or other matter), collisions will return He\* to its normal state (gaseous He) with an impressive release of energy (about 20 eV per atom, or 480 MJ/kg) that can be used for propulsion. Xenon and krypton are used as working fluids in ion and Hall thrusters.

## 1.1 Metals of the Second and Third Row of the Periodic Table of Elements

The following sections discuss the metals and metalloids of the second and third row and the first, second, third and fourth column of the periodic table of the elements. These metals and metalloids are rarely used as fuels by themselves but are most often used as additives to other propellants to increase the heat of combustion and also increase the specific impulse. All metals that leave metal oxides or metal fluorides as condensable species in the exhaust actually cause some performance loss due to two-phase flow. Slag depositions on critical orifices and in the nozzle throat also may cause operational problems with rocket engines that have to be used more than once.

## 1.2 Metal Hydrides

Metal hydrides will be presented in section “Metal Hydrides” immediately following the sections on metals. Boron does not count as a metal, but it is a non-metal, a metalloid, and it was assigned to its own chapter in this volume, the *Encyclopedia of Liquid Fuels* (although it is not a liquid). Boron hydrides are discussed in a separate chapter “Boranes.”

## 2 Lithium Metal

After helium, the next element in line in the periodic table of elements is lithium, starting the second row of the system. Lithium is a metal in the group of alkali metals and forms many salts with acids. It forms oxides and nitrides with oxygen and nitrogen. It forms a hydride with hydrogen which is not a covalent hydride but a saline hydride in which lithium is a positive ion and hydrogen is a negative ion.

### 2.1 Lithium and Lithium Compounds

Lithium is a potential rocket propellant both in its form as a metal as well as in the form of saline hydrides, such as lithium hydride LiH or complex hydrides such as lithium boron hydride (lithium borohydride) LiBH<sub>4</sub>. The low atomic mass of lithium, 6.941 g/g-atom, maintains the low average molecular mass of the exhaust products and allows the achievement of high specific impulses. Lithium perchlorate is a promising oxidizer since it contains a high percentage of useable oxygen (60.15 mass-% oxygen in LiClO<sub>4</sub>). There are many summary publications that describe the properties and application of lithium and lithium compounds [1–4].

Lithium compounds are used for batteries, air conditioners/chillers, lightweight alloys, construction materials, medicines, fine chemicals, glass and ceramics, lithium

greases and lubricants, also in the form of lithium hypochlorite for swimming pool water “shock” treatment, and polymerization catalysts. In addition to its potential use as a propellant, lithium in the form of lithium-aluminum alloys or lithium-magnesium alloys has recently found widespread applications as lightweight alloys for rocket propellant tanks and structural elements where lightweight structures are at a premium to increase the useful payloads.

Until 1940 lithium compounds were only used for medicinal purposes. When industry started using lithium soaps as high-temperature lubricants, the demand for lithium increased substantially. Lithium-ion batteries have high cell voltage and good long-term storage properties (slow self-discharge) and initially were often used in emergency locating beacons of aircraft and marine vessels. In the meantime, lithium-ion batteries are now widely used in electric automobiles, but the transportation of lithium-ion batteries in aircraft has been outlawed after several incidents of fires in cargo holds.

Lithium deuteride  ${}^6\text{Li}^2\text{H}$  or lithium tritide  ${}^6\text{Li}^3\text{H}$  can be used in thermonuclear fusion weapons and fusion reactors. Lithium deuteride is a potential fuel for controlled fusion nuclear reactors.

## 2.2 Occurrence of Lithium

Lithium occurs naturally in the form of lithium ores but never as the free metal. Lithium ores are in the form of lepidolith, a lithium-potassium-aluminum silicate containing 2–7 mass-% Li, often accompanied by spodumene containing 3–7.6% Li and petalite, a lithium aluminum phyllosilicate mineral,  $\text{LiAlSi}_4\text{O}_{10}$ , containing 2.27% Li. Lithium demand has skyrocketed in the early 2000s due to increased demand for lithium-ion batteries in portable electronic devices and electric cars or even passenger airplanes [5]. Further expansion of electric cars and airplanes with lithium batteries may be delayed by the limited availability of lithium.

There is some disagreement on whether the supply of lithium is adequate to support a future global fleet of electric vehicles. A comprehensive supply analysis of the global lithium resources and a comparison to global lithium demand from 2010 to 2100 assumed rapid and widespread adoption of electric vehicles but estimates of global lithium resources have reached very different conclusions [6]. Some investigators concluded that even with a rapid and widespread adoption of electric vehicles powered by lithium-ion batteries, lithium resources should be sufficient to support demand until at least the end of this century [7]. In the future, diverting any amount of lithium to use it as a high-energy rocket propellant on a larger scale would only aggravate the supply situation.

Hardrock mining of pegmatites has been the traditional source for lithium products, in particular from open-pit mines in North Carolina in the USA, Bikita in Zimbabwe, Manitoba, Canada, and in Western Australia; however, the North Carolina

spodumene mines are being abandoned in favor of South American sources. The two North Carolina pegmatite operations closed with the development of lower cost sources in Chile but could be reactivated, should a massive demand materialize and prices rise as a result. Cyprus Foote Minerals closed its spodumene mine in 1986 to concentrate its efforts on brines of the Salar de Atacama in Chile together with its existing brine operation at Silver Peak, Nevada. Sociedad Quimica y Minera (SQM) is a major producer of nitrates and iodine in Chile and produces potassium and lithium salts as by-products. Lithium Corporation of America operated a pegmatite mine in Bessemer City, Gaston Co., North Carolina, USA until the late 1990s. It was located about 6 miles northeast of the Foote mine. There have been many changes in the lithium exploration and mining business during the past years. Lithium mines that were dormant for a while are now re-opened because there is a high demand of lithium for batteries.

### 2.3 Production of Lithium Metal

There are several leading industrial international and national companies in the field of lithium compounds. The most common form of lithium in the as-processed and enriched form from ores is lithium carbonate. Lithium metal is made from a melt of lithium chloride by electrolysis.

### 2.4 Physical Properties of Lithium Metal

Lithium is the lightest metal in the periodic table of elements. Its density is so low that it even floats on water (but not for long because it will react with water forming lithium hydroxide and hydrogen gas). The physical properties of lithium metal are summarized in Table 1. See also [8].

**Table 1:** Physical properties of lithium metal.

| Property               | SI Units                                  | Other Units                                  |
|------------------------|-------------------------------------------|----------------------------------------------|
| Atomic mass            | 6.941 Atomic mass units                   | 144.07 g-atom/kg                             |
| Melting point          | 453.69 K                                  | 180.54 °C                                    |
| Boiling point          | 1620 K                                    | 1347 °C                                      |
| Density at 298 K       | 0.534 g/cm <sup>3</sup>                   | —                                            |
| Heat capacity at 298 K | 24.63 J mol <sup>-1</sup> K <sup>-1</sup> | 5.887 cal mol <sup>-1</sup> °C <sup>-1</sup> |
| Heat of fusion         | 3.00 kJ/mol                               | 0.7171 kcal/mol                              |
| Heat of evaporation    | 147.1 kJ/mol                              | 35.16 kcal/mol                               |

### 2.4.1 Vapor Pressure of Lithium

The vapor pressure of molten lithium can be calculated from an Antoine equation

$$\log_{10}(P) = A - [B/(T + C)]$$

where  $P$  is the vapor pressure in bar and  $T$  is the temperature in K. The constants  $A$ ,  $B$ , and  $C$  are listed in Table 2 for two different temperature ranges. See also [9].

**Table 2:** Antoine equation constants for lithium.

| Temperature range, K | A       | B        | C        |
|----------------------|---------|----------|----------|
| 298–1600             | 4.98831 | 7918.984 | −9.52    |
| 1204–1353            | 1.58992 | 1603.966 | −711.088 |

Data source: [10]; Coefficients calculated by NIST from author's data.

### 2.4.2 Viscosity of Lithium

Molten lithium has been considered as a coolant for nuclear reactors. Molten lithium would be a key ingredient for  $F_2/H_2/Li$  tripropellant combinations that would give the highest specific impulse achievable with any chemical propellant. Rocket engines have been operated on molten lithium as a fuel. The viscosity of molten lithium has been measured [11, 12].

### 2.4.3 Surface Tension of Lithium

The effects of oxygen and nitrogen contamination on surface tension and contact angle of molten lithium were measured at 479–836 K (206–563 °C) [13]. The maximum bubble pressure method was used for measuring the surface tension.

### 2.4.4 Heat Capacity of Lithium

The heat capacity of lithium as a function of temperature can be calculated from the following polynomial Shomate equation:

$$C_p^\circ = A + B \times \tau + C \times \tau^2 + D \times \tau^3 + E/\tau^2$$

where  $C_p$  is the molar heat capacity in  $J\ mol^{-1}\ K^{-1}$ ,  $\tau$  is the temperature in kelvin divided by 1000 and  $A$ ,  $B$ ,  $C$ ,  $D$ , and  $E$  are constants listed in Table 3 for three different physical states and four different temperature ranges.

**Table 3:** Thermodynamic property polynomial equation coefficients for lithium.

| Physical state | Solid     | Liquid     |           | Gas       |
|----------------|-----------|------------|-----------|-----------|
| Temperature, K | 298–453   | 453.69–700 | 700–1620  | 1620–6000 |
| A              | 169.5520  | 32.46972   | 26.00896  | 23.33408  |
| B              | –882.7110 | –2.635975  | 5.632375  | –2.772423 |
| C              | 1977.438  | –6.327128  | –4.013227 | 0.767421  |
| D              | –1487.312 | 4.230359   | 0.873686  | –0.003595 |
| E              | –1.609635 | 0.005686   | 0.344150  | –0.035246 |

Data source: [10]

Molten lithium and lithium alloys have been evaluated as both coolant, heat transfer fluid, and neutron moderator in nuclear reactors (SP-100 space nuclear power supply), and its thermodynamic properties for that application have been thoroughly evaluated [14]. Compilations of properties including density, vapor pressure, viscosity, surface tension, electrical conductivity, thermal conductivity, thermal diffusivity, heat capacity, and enthalpy were provided for temperatures between the melting point and boiling point of lithium and other alkali metals [15, 16]. It is unlikely that anyone will be able again to pump liquid lithium as a rocket propellant in tripropellant or pentaplex propellant combinations, but just in case, the transport properties of liquid lithium are available [17].

## 2.5 Chemical Properties of Lithium Metal

Lithium, Li, CAS RN [7439-93-2], is a soft, metallic-shiny metal that is stable in dry air. Freshly cut surfaces will quickly discolor to a dull gray due to interaction of the metal with moisture in the air. Once ignited, lithium burns in air with a pink-red flame. Lithium cannot be melted under a nitrogen “inert gas” atmosphere because molten lithium reacts with nitrogen to form the nitride  $\text{Li}_3\text{N}$ . If a chunk of lithium gets thrown on water, it will float and develop hydrogen gas, but the metal will not melt like sodium and potassium usually do. Lithium bar or lithium extruded wire is usually stored under oil to protect it from the moisture of the air.

Lithium forms salts with many acids. Lithium ions in salts are always in the oxidation state of 1+ as the lithium  $\text{Li}^+$  cation. Lithium salts are colorless unless the anion originates from a colored acid, like  $\text{HCrO}_4$ . Most lithium salts are water-soluble, but many have limited solubility and they are more similar to those of magnesium due to a diagonal relationship in the periodic table of elements (“Schräganalogie” in German). For instance, lithium carbonate or lithium phosphate is not very soluble in water and in this respect resembles magnesium carbonate or magnesium phosphate.

## 2.6 Handling of Lithium

Lithium must be stored under dry conditions and preferably under a protective atmosphere of argon. Molten lithium reacts with oxygen **and** nitrogen. Lithium metal bars are often stored under a heavy hydrocarbon oil to protect them from the atmosphere. Lithium fires can be extinguished by smothering them with carbon dust [18].

## 2.7 Toxicity Properties of Lithium

Overdoses of lithium salts cause vomiting, tremors, kidney damage, unconsciousness and cardiac arrest. Small doses of lithium salts are used as antidepressants.

## 2.8 Use of Lithium as a Rocket Propellant

It has been attempted to use molten lithium as a liquid rocket propellant (see future volume *Encyclopedia of Hypergolic Bipropellant Combinations*), but the melting, feeding and injection of molten lithium into a rocket engine is a very difficult task. The metal may solidify in places where it was not supposed to and may clog lines and injector orifices. There is experience with pumping of molten alkali metals in cooling circuits of nuclear reactors. The other use of lithium as a rocket propellant would use lithium in combination with a binder as a solid in hybrid rocket engines or in tribrid or pentaplex rocket engines. Another potential use of lithium metal as a rocket fuel would be in the form of a solution in liquid ammonia (see chapter “Ammonia”). It is very unusual that a metal dissolves in a solvent without a chemical reaction. The lithium metal shares some of its electrons with the liquid ammonia solvent, causing the liquid to assume a deep blue color. At very high concentrations, the surface of the solutions has a copper-colored metallic sheen.

## 3 Beryllium and Beryllium Compounds

Beryllium and beryllium compounds in combination with hydrogen-rich fuels will theoretically enable the rocket propellant chemist to achieve the ultimate high in chemical propellant specific impulse; however, the extreme toxicity of beryllium exhaust prevents the widespread use of beryllium propellant combinations, at least for earthbound applications. Besides that, beryllium is available only in limited quantities.

### 3.1 Production of Beryllium and Beryllium Compounds

There have been many changes in the beryllium mining, processing, and forming industries. Beryllium Manufacturing Corp. was founded in 1974. The company's line of business includes the manufacturing of aircraft parts and equipment. Brush Wellman Inc. is the world's leading producer of pure beryllium and beryllium products [19]. Brush Wellman Beryllium Products is an integrated global producer of beryllium-based metals and metal matrix composites. The Brush Wellman Beryllium Products industrial plant in the remote Sevier Desert of western Utah is one of the only sources of concentrated beryllium in the world. The plant is a mill and finishing facility for beryllium, the high-strength, lightweight metal used in military, aerospace and medical industries. The ore for the plant comes from Brush Wellman's mine, located in the Topaz-Spor Mountains, 50 miles west, which is North America's only developed source for the metal. The facility is located here due to the remoteness of the area, as beryllium dust is highly toxic, and the proximity of a source of power, the Intermountain Power Project, a coal-fired power plant located a few miles away.

American Beryllia Inc. is a manufacturer and distributor of beryllium oxide ceramic (BeO) heat sinks, crucibles, rods, washers, thermocouple tubing and custom-made substrates for a diverse range of aerospace, defense, electronic, and commercial applications [20]. Beryllium oxide, commonly called beryllia, is a ceramic material that offers a combination of desirable properties not found in any other ceramic material. Distinguished by excellent thermal conductivity, BeO ceramic retains dielectric constant, loss factor, and dielectric strength in the range of most electrical insulators. Along with good mechanical strength and stiffness to weight ratios, this unique combination of properties provides designers with a material that can reduce the size of heat generating circuitry while retaining essential high-power capability and improved thermal stability. Typical applications of BeO ceramics include heat sinks in high power electronics and semiconductors and use as a heat dissipation medium in a wide range of miniaturized circuitry applications in the defense, aerospace, and commercial markets.

Pure beryllium metal is used in the manufacture of aircraft disc brakes, nuclear weapons and reactors, missile parts, heat shields, X-ray machine parts, mirrors, and spacecraft. In addition to its controversial use as a consumable rocket propellant, beryllium metal also has found applications as lightweight alloy in spacecraft structures. For instance, the engine mounting bracket on Magellan Venus Orbiter reaction control monopropellant thruster modules was made from a beryllium alloy to allow improved thermal management while in orbit around Venus.

Brake drums that must take high heat loads, such as those once flown on Space Shuttle, have been made from beryllium alloys. Beryllium/copper alloys are used in non-sparking tools.

The use of beryllium as a rocket propellant for outer-space applications where specific impulse is at a premium and toxicity is not a concern is still hampered by its high price (\$ 231/lb as of 2016) and limited availability.

### 3.2 Occurrence of Beryllium

Beryllium occurs in the form of beryl mineral containing ~14% BeO corresponding to 3.4–5% Be. Beryl occurs in many places, usually accompanied by pegmatite. For a long time the separation of the ore from the tailings was done by hand. The United States has very little beryl resources that can be economically hand sorted from pegmatite deposits. Large beryl deposits were found in Brazil and Argentina. The Spor Mountain area in Utah, an epithermal ore deposit, contains a large bertrandite resource which is being mined. Many fly ashes from coal-fired power plants contain 0.1–1% BeO which is a toxicity concern.

### 3.3 Processing of Beryllium Ores into Beryllium Metal

Beryllium ores are first processed to BeO or BeF<sub>2</sub> from which the metal can be obtained by reduction with molten sodium or by electrolysis of molten beryllium salts. The main beryllium producer in the US as of 2010 was Brush Wellman in Utah. The US beryllium metal production in 2016 was 190 metric tons.

For using beryllium as a rocket propellant, it is important to have it in the form of small particles that burn completely without being encrusted with an oxide layer which results in incomplete combustion. Beryllium powder can be made by an amalgam method [21, 22], or by electrolysis of a beryllium chloride-sodium chloride molten eutectic mixture with a mercury cathode and beryllium anode [23, 24].

### 3.4 Physical Properties of Beryllium

Beryllium, CAS RN [7440-41-7], is a lightweight metal with remarkable strength, also when used as an alloying metal with other metals. The physical properties of beryllium are summarized in Table 4.

The heat capacity of beryllium as a function of temperature can be calculated from the following polynomial Shomate equation:

$$C_p^\circ = A + B \times \tau + C \times \tau^2 + D \times \tau^3 + E/\tau^2$$

where  $C_p$  is the molar heat capacity in J mol<sup>-1</sup> K<sup>-1</sup>,  $\tau$  is the temperature in kelvin divided by 1000 and A, B, C, D, and E are constants listed in Table 5 for four different temperature ranges.

**Table 4:** Physical properties of beryllium.

| Property                      | SI Units                                  | Other units                                                  |
|-------------------------------|-------------------------------------------|--------------------------------------------------------------|
| Atomic mass                   | 9.013 Atomic mass units                   |                                                              |
| Melting point                 | 1556 K                                    | 1283 °C                                                      |
| Boiling point                 | 2757 K                                    | 2484 °C                                                      |
| Density at 293 K              | 1.84 g/cm <sup>3</sup>                    | —                                                            |
| Heat capacity at 298 K        | 16.45 J mol <sup>-1</sup> K <sup>-1</sup> | 3.932 cal mol <sup>-1</sup> °C <sup>-1</sup>                 |
| Heat of fusion                | 11.7 ± 2.1 kJ/mol                         | 2.8 ± 0.5 kcal/mol                                           |
| Heat of sublimation           | 327 kJ/mol                                | 78.254 kcal/mol                                              |
| Heat of combustion            | 565 kJ/mol                                | 135 kcal/mol                                                 |
| Thermal conductivity at 273 K | 1.6096 W cm <sup>-1</sup> K <sup>-1</sup> | 0.3847 cal cm <sup>-1</sup> s <sup>-1</sup> °C <sup>-1</sup> |

**Table 5:** Thermodynamic property polynomial equation coefficients for beryllium.

| Physical state       | Solid     |           | Liquid    | Gas       |

Data source: [10]

### 3.5 Chemical Properties of Beryllium

Summaries on the chemistry of beryllium and beryllium compounds were published in [25–28]. There are numerous books devoted to beryllium that can serve as the source of additional information [29].

#### 3.5.1 Analysis of Beryllium

The analysis of beryllium content in the air at places of employment is an important part of the precautions taken against the accidental poisoning by airborne beryllium. The methods used for grab samples (air filters, wipes, biological specimens) are emission spectrography [30, 31], or gas chromatography [32] or wet spectrophotometric methods; [33–35].

### 3.5.1.1 Monitoring of Workplace Beryllium Concentrations

Workplace concentrations of beryllium need to be measured regularly to show compliance with government regulations and to catch any sloppy housekeeping that may develop after workers become used to the hazard. Workplace concentrations are measured both in air samples and in wipe samples. Wipe samples are taken with moist filter paper on floors, shelves and on top of cabinets in work areas. The beryllium concentration in wipe samples should not exceed  $2\mu\text{g}/\text{m}^2$ . Clothing of employees leaving the plant should be inspected periodically for beryllium contamination.

Concentration of airborne particulate beryllium is measured by passing a known volume of air through a micro-pore filter and leaching the filter with acid to extract all acid-soluble compounds. It would make most sense to place the intake of the air sampler at the nose level of the personnel we are trying to protect.

### 3.5.1.2 Direct Reading Beryllium Contamination Monitors

There are no off-the-shelf direct-reading analyzers on the market which give a direct readout of the beryllium concentration in the air at levels near the recommended TLV-MAC. It has been attempted to develop continuously operating direct-reading emission spectrometers which aspirate air and pass it through an electric discharge between two electrodes [36] or by atomic absorption spectrometry in a nitrous oxide/acetylene flame [37]. Sensitivity is about  $0.5\mu\text{g}/\text{m}^3$  beryllium. Another direct-reading method is laser-induced-breakdown spectroscopy [38]. The limit of detection for beryllium in air was  $0.5\text{ ng/g}$ , which is one third of the Occupational Safety and Health Administration (OSHA) limit for the 8-h average exposure to beryllium. Another direct-reading continuous analysis method is by microwave-induced plasma spectroscopy [39].

### 3.5.2 Reactions of Beryllium

Beryllium metal burns in atmospheres of oxygen or carbon dioxide, it would thus burn in the atmosphere on Mars. The rates of oxidation are dependent on the moisture content of the atmosphere [40–43]. Oxide layers retard the combustion of beryllium [44–46].

### 3.5.3 Applications of Beryllium in Rocket Propellants

Beryllium metal can be used as a high-energy additive to solid rocket propellants or as a component in hybrid, tribrid, and pentaplex propellants [47]. The first major solid propellant beryllium program was operated by the US Air Force. Another method of using beryllium as a small-particle size powder is to suspend it in gelled hydrocarbon fuel slurries, thus substantially increasing the heat of combustion.

### 3.6 Toxic Properties of Beryllium and Beryllium Compounds

Beryllium was known for many years as “glucinium,” a name based on its sugary taste. Obviously, nobody would want to repeat this taste experiment! Although it is unlikely that beryllium will again be evaluated as a rocket propellant, we have included a chapter on beryllium toxicity because beryllium is continued to be used in other lightweight components of spacecraft. Summaries recommended for further study on toxicity of beryllium and beryllium compounds are in [48, 49].

#### 3.6.1 History of Beryllium Toxicity and Epidemiology

Prior to 1933 it was not known that beryllium compounds are toxic and can cause severe acute and chronic fatal poisonings in workers exposed to the metal, beryllium-containing minerals and other compounds.

In the 1930s, workers in a beryllium-processing factory in Germany fell ill with symptoms similar to chlorine or phosgene poisonings. In addition, they developed skin eczema, mostly on unprotected parts of the skin in the face and on the hands. A total of 17 cases were reported between 1933 and 1942, including 3 fatalities. Initially the problems were blamed on beryllium fluoride which was a common thread in the exposure history of all cases, but soon thereafter cases developed where workers had been exposed to other beryllium compounds that had been considered harmless up to that time.

The German experience was either insufficiently documented or had not entered the international medical literature, because in the years after WW-II a group of 38 workers out of a cohort of 170 workers in a US ore processing plant came down with lung sickness and 5 of them perished. It was not until 1948 that occupational hygiene supervisory agencies issued guidelines for avoiding the exposure to beryllium and the number of further poisonings decreased (See Section 3.6.8). Berylliosis, or chronic beryllium disease (CBD), is a chronic allergic-type lung response and chronic lung disease caused by exposure to beryllium and its compounds, a form of beryllium poisoning. The condition is incurable but symptoms can be treated.

In 1952 a “Beryllium Case Registry” (BCR) was founded at Massachusetts General Hospital in Boston which maintained a database about victims and their exposure history [50–54]. Anybody who was promoting the use of beryllium-containing rocket propellants in the 1950s and 1960s should have been aware of the toxicity hazards of this chemical. Additional surveys on beryllium toxicity are [55, 56].

#### 3.6.2 Types of Beryllium Poisoning

There are at least three types of beryllium poisoning to worry about: acute toxicity, chronic toxicity, and skin irritation. Acute beryllium poisoning is the result of brief inhalation of high concentrations of volatile beryllium compounds (e.g., BeF<sub>2</sub>, BeSO<sub>4</sub>), occasionally also caused by inhalation of dust. Symptoms are dry cough, pneumoni-

tis, and a permanent alteration of the lung structure which can be recognized in X-ray shadowgraphs. The symptoms will appear soon, usually within 1 week, after the exposure and can end either fatally or allow seemingly complete recovery; however, as of 1965, the BCR contained 22 cases in which an acute beryllium poisoning led to subsequent chronic poisoning symptoms. See also [57].

### 3.6.3 Symptoms of Beryllium Poisoning

The autopsy of victims of acute beryllium poisoning revealed drastically altered lung tissue, enlarged lungs with the vesicles filled completely or partially with fluid. Chronic berylliosis symptoms are similar to idiopathic sarcoidosis. Differences were recognized only after the epidemic disease occurrence in the fluorescent light bulb industry due to widely used beryllium-containing phosphors was revealed. As of 1983, of a cohort of 23000 potentially exposed workers in the fluorescent light bulb industry, 207 developed chronic beryllium disease.

Symptoms of victims of chronic beryllium poisonings are not quite distinct. There were several cases where not workers, but neighbors to the factory living downwind of the installation came down with cases of berylliosis. The symptoms were sudden weight loss, loss of appetite, cough, shortness of breath, and changes in the lung structure similar to those observed as the result of acute poisoning. Chronic beryllium poisoning often leads to long-lasting lingering illness and high mortality [58–61].

Chronic beryllium disease is predominantly a pulmonary granulomatosis where symptoms usually include dyspnea and cough [62]. Fever, anorexia and weight loss are common. Skin lesions are the most common extrathoracic manifestation. Granulomatous hepatitis, hypercalcemia, and kidney stones can also occur. Radiographic and physiologic abnormalities are similar to those in sarcoidosis but are characterized by well-formed granuloma.

Beryllium continues to have a wide range of industrial applications. Exposure to beryllium can lead to beryllium sensitization (BeS) and chronic beryllium disease (CBD). The beryllium lymphocyte proliferation test is used for both medical surveillance and the diagnosis of BeS and CBD [63]. A confirmed abnormal beryllium lymphocyte proliferation test without evidence of lung disease is diagnostic of BeS. BeS with evidence of a granulomatous inflammatory response in the lung is diagnostic of CBD. The determinants of progression from BeS to CBD are uncertain, but higher exposures and the presence of a genetic variant in the HLA-DP  $\beta$  chain appear to increase the inherited risk. Periodic evaluation of affected individuals can detect disease progression (from BeS to CBD, or from mild CBD to more severe CBD). Corticosteroid treatment is typically administered when a patient with CBD exhibits evidence of significant lung function abnormality or decline. Medical surveillance in workplaces that use beryllium-containing materials can identify individuals with BeS and at-risk groups of workers, which can help prioritize efforts to reduce inhalational and dermal exposures.

In order to help determine the steps necessary to protect its workforce from the adverse effects of exposure to beryllium used in military aerospace applications, the US Air Force requested that the US National Research Council Committee on Toxicology conduct an independent evaluation of the scientific literature on beryllium, provide risk estimates for cancer and non-cancer health end points, and make recommendations about specific tests for surveillance and biomonitoring of workers [64]. The request specified that two reports be produced to accomplish those tasks. The first was to provide a review of the scientific literature on beryllium, and the second to expand more critically on the review in considering the maximum chronic inhalation exposure levels that are unlikely to produce adverse health effects, in estimating carcinogenic risks, and in providing guidance on testing methods for surveillance and monitoring of worker populations and other specific issues detailed in the statement of task. The first report identified the available toxicologic, epidemiologic and other literature on beryllium that is most relevant for addressing the problem, focusing primarily on BeS, CBD, and cancer.

#### **3.6.4 Epidemiological Studies of Prevalence of Beryllium Disease**

Epidemiological studies of workers at beryllium processing plants were eventually expanded to their family members and people living near a beryllium processing plant, but not working there [65].

In order to describe relative hazards in sectors of the beryllium industry, risk factors of beryllium disease and sensitization related to work processes were sought in a beryllium manufacturing plant producing pure metal, oxide, alloys, and ceramics [66]. All 646 active employees were interviewed. Beryllium sensitization was ascertained with the beryllium lymphocyte proliferation blood test on 627 employees. Clinical evaluation and bronchoscopy were offered to people with abnormal test results. Industrial hygiene measurements related to work processes taken in 1984–1993 were reviewed: 59 employees (9.4%) had abnormal blood tests, 47 of whom underwent bronchoscopy, 24 new cases of beryllium disease were identified, resulting in a beryllium disease prevalence of 4.6%, including 5 known cases (29/632). Employees who had worked in ceramics had the highest prevalence of beryllium disease (9.0%). Employees in the pebble plant (producing beryllium metal) who had been employed after 1983 also had increased risk, with a prevalence of beryllium disease of 6.4%, compared with 1.3% of other workers hired in the same period, and a prevalence of abnormal blood tests of 19.2%. Logistic regression modelling confirmed these two risk factors for beryllium disease related to work processes and the dependence on duration of exposure at the pebble plant. The pebble plant was not associated with the highest gravimetric dust measurements reported since 1984.

### 3.6.5 Animal Exposure Tests with Beryllium

Numerous animal exposure tests to different forms of beryllium and under different routes of administration have been conducted in order to have a better understanding of the effects of this poison in humans. Two beagle dogs were exposed by the natural respiratory route to rocket exhaust fumes containing beryllium oxide, beryllium fluoride, and beryllium chloride [67]. After a 3-year post-exposure observation period, the lung tissue was examined electron microscopically. Beryllium particles and small agglomerates less than  $1\mu$  in size were deposited in lysosomes in the cytoplasm of histiocytes in the interstitium of the septa. They were closely associated with collagen bundles several microns wide and with increases in numbers of septal capillaries. The lesions were more typical of the classical reaction to a foreign body than immunologic in character and represented an early form of chronic beryllium disease.

Groups of rats were exposed once by nose only for 50 min to a mean concentration of  $800\mu\text{g}/\text{m}^3$  of beryllium metal (initial lung burden,  $625\mu\text{g}$ ) to characterize the acute toxic effects within the lungs and histological changes within the lungs and enzyme changes within bronchoalveolar lavage fluid were evaluated at 3, 7, 10, 14, 31, 59, 115, and 171 **days post-exposure (dpe)** [68]. Beryllium metal-exposed rats developed acute, necrotizing, hemorrhagic, exudative pneumonitis and intra-alveolar fibrosis that peaked at 14 dpe. By 31 dpe, inflammatory lesions were replaced by minimal interstitial and intra-alveolar fibrosis. Necrotizing inflammation was observed again at 59 dpe which progressed to chronic-active inflammation by 115 dpe. This inflammation worsened progressively, as did alveolar macrophage and epithelial hyperplasia, becoming severe at 171 dpe. Results indicated that inhalation of beryllium metal by rats resulted in severe, acute chemical pneumonitis that was followed by a quiescent period of minimal inflammation and mild fibrosis. Progressive, chronic-active, fibrosing pneumonitis was observed later. Chronic beryllium lung disease in man is an immunologically mediated granulomatous lung disease, whereas beryllium-induced lung lesions in rats appeared to be due to direct chemical toxicity and foreign body type reactions.

### 3.6.6 Threshold Concentrations

Based on the cases observed in the US, the threshold concentration for acute poisonings was assumed to be above  $0.1\text{mg Be}/\text{m}^3$  for an 8-h work shift. In 3 cases of acute accidental exposure of only 20 min at a concentration of  $0.45\text{--}0.6\text{mg Be}/\text{m}^3$ , the first symptoms were observed within 72h of the incident.

The OSHA has set a limit of  $2\mu\text{g beryllium}/\text{m}^3$  of workroom air for an 8-h work shift. The National Institute of Occupational Safety and Health (NIOSH) recommends a standard for occupational exposure of  $0.5\mu\text{g beryllium}/\text{m}^3$  of workroom air during an 8-h shift to protect workers from the increased cancer risk associated with beryllium exposure [69]. The EPA restricts the amount of beryllium released into the

air to 0.01 µg beryllium/m<sup>3</sup> of air, averaged over a 30-day period. The EPA has set a maximum allowable amount of 0.004 mg/L beryllium in drinking water.

The susceptibility of workers to beryllium poisoning is quite different. Some workers had been unknowingly exposed for more than 10 years and survived, whereas others fell ill soon after they started working in the factory. As of 1965, there were 42 known cases (with 50% of these with fatal endings) of persons who had lived within 1.2 km of a beryllium factory and had never worked there. The downwind concentrations were probably of the order of 0.01 – 0.1 µg Be/m<sup>3</sup>.

### 3.6.7 Skin Effects

Beryllium compounds can cause contact dermatitis within a few days after exposure, evidenced by dermatitis and conjunctivitis. The lesions will heal soon after the exposure has been discontinued [70].

There are various references to sensitization to beryllium in the literature. Since introducing a patch test for patients with suspected sensitization to metals, three cases of sensitization to beryllium were found [71]. Of these three cases, the first two were regarded as relevant sensitization. Occupational chronic beryllium disease includes cutaneous irritation and skin exposure may cause the disease [72].

### 3.6.8 Government Regulations and Recommendations

The US Atomic Energy Commission formed a “Beryllium Advisory Committee” in 1948 which issued the following recommendations:

1. The airborne concentration of beryllium in workspaces shall not exceed 2 µg/m<sup>3</sup>, averaged over an 8-h shift.
2. The concentration shall not exceed 25 µg/m<sup>3</sup> at any time.
3. If the average concentration during 3 months exceeds 2 µg/m<sup>3</sup> but remains below 5 µg/m<sup>3</sup>, or if a single sample exceeds 25 µg/m<sup>3</sup>, work may be continued while corrective steps are taken to reduce the airborne concentration, but all workers must wear respiratory protection.
4. For exposure of the general public, the concentration shall not exceed 0.01 µg/m<sup>3</sup> at any time.

Since the introduction of these regulations (recommendations??) there were no further beryllium poisoning incidents at AEC facilities [73].

The following is a condensed version of information taken from the [www.chemicalindustryarchives.com/](http://www.chemicalindustryarchives.com/) and [www.chemicalindustryarchives.com/dirtysecrets/beryllium/1.asp](http://www.chemicalindustryarchives.com/dirtysecrets/beryllium/1.asp) web sites and provides some revealing background information on the efforts to establish safe beryllium exposure limits. It appears that sometimes the needs for national security in support of the atomic weapons program have taken priority over occupational safety concerns.

Brush Wellman began researching beryllium in 1921, opened its first commercial facility to produce the metal in 1931 and continues to operate to this day. The primary consumer of beryllium – it was the top consumer until a recent surge in commercial uses – has been the US government, which first used the metal to build better atomic weapons. Workers were not educated about the dangers of beryllium dust, nor were they aware that the government and industry knew of workers dying from on the job exposure. Over 40 cases of chronic beryllium disease, including 7 deaths and about 500 cases of acute disease, including nearly a dozen deaths, had been reported in the US by September 1947.

In 1948, additional cases of beryllium disease, including cases among non-worker residents living near the beryllium plants, became known. The Atomic Energy Commission, which was the largest consumer of beryllium at the time, worked out a deal with Brush, agreeing to contract with the company to build and operate a government-owned beryllium plant. At the same time, the AEC also contracted with the Beryllium Corporation of America (Berylco), Brush's main competitor, and those two companies promised to provide all of the government's beryllium needs. While the contract included a clause limiting airborne levels of beryllium to a maximum of 2.0 micrograms of beryllium per cubic meter of air ( $\mu\text{g}/\text{m}^3$ ), this standard was never enforced by the AEC [74]. Brush and the AEC were aware that even the  $2.0\mu\text{g}/\text{m}^3$  standard was not necessarily safe. One of the reports stated: "It is believed that the two microgram figure has not been proven with any degree of technical rigidity to be an absolute safe maximum concentration." Despite this knowledge, neither Brush nor the AEC ever enforced the questionable  $2.0\mu\text{g}/\text{m}^3$  standard.

When the OSHA proposed a tightening of the standard for airborne beryllium concentrations in the 1970s, Brush Wellman went on the offensive. Brush urged the Department of Energy (DOE) and Department of Defense (DOD) to drop the proposed OSHA standard, threatening to quit the business if the tighter standard was promulgated. The complaints compelled the Secretary of Energy to write to the Secretary of Labor declaring that the proposed regulations would threaten national security. He insisted that beryllium was vital to the development of nuclear weapons and that its continued production could not be compromised. The Secretary of Labor agreed, writing in his response that "the Department [of Labor] has no intention of significantly or adversely affecting key national defense programs."

The  $2.0\mu\text{g}/\text{m}^3$  standard is still the law for workplace exposures [See 29 C.F.R. 1910.1000 (2001)], even though many scientists dispute the safety of this standard. As for those who contract beryllium disease, it appears that about one third die from it, another third are disabled, and the rest appear to live relatively healthy lives. Doctors still are not exactly sure how to explain the different reactions or why some are more susceptible to the disease than others. For victims of the disease, the symptoms can be treated with powerful steroids, although beryllium disease itself remains incurable to this day.

### 3.6.9 Atmospheric Diffusion of Beryllium Exhaust Clouds

The US Air Force conducted atmospheric diffusion of beryllium exhaust clouds in remote areas by releasing clouds under carefully controlled and highly instrumented conditions. The project was called by the code name Project ADOBE for **A**tmospheric **D**iffusion of **B**eryllium [75–77]: 57 sets of field data were collected from 250–350 air samplers per test using solid rocket motors containing from 45–1812 kg (100–4000 lb) of propellant containing beryllium. Surveys covered a 25 square mile sector, covered with an array of 492 air samplers (250–350 samplers per test) located from 600 to 9600 m from the source. Analysis of exhaust samples showed that beryllium oxide is essentially insoluble and of low toxicity [78].

## 3.7 Handling and Processing of Beryllium and Beryllium Compounds

The main concern during the processing of beryllium and beryllium compounds is the avoidance of dust. Solid rocket propellant preparation with beryllium powder and static firing of rocket motors with beryllium-containing propellants required special safety precautions [79].

### 3.7.1 Marking of Designated Beryllium Workspaces

It is recommended to restrict work with beryllium to a designated beryllium work zone with precautions that prevent the spread of contamination throughout the building. The entry to the potentially beryllium-contaminated area should go through air locks where operators can change their work clothes and take showers before they leave work. Change rooms have a clearly marked “clean” and a “potentially contaminated” entrance.

### 3.7.2 Storage of Beryllium and Beryllium Compounds

Beryllium and beryllium compounds should be stored away from other chemicals and only in fire-proof cabinets.

### 3.7.3 Design of Workplaces for Handling Beryllium

Workplaces for beryllium and beryllium compounds should have unidirectional ventilation like in a laminar flow bench [80]. Some beryllium compounds are so toxic or sensitive to air and moisture that they need to be handled only in glove boxes under an inert atmosphere. The process most likely to cause toxicity problems is the weighing and packaging of fine powders.

### 3.7.4 Control of Beryllium Fires

As part of the SNAP-10A (Space Nuclear Auxiliary Power) project, beryllium hazards were measured in four controlled fires. Over 125 air samples and swipe samples were taken during the tests. Only eight samples showed concentrations of Be above the minimum detectable level [81]. Beryllium fires can be extinguished by smothering them with carbon dust [18].

## 3.8 Applications of Beryllium as Rocket Propellant

The addition of beryllium to solid or liquid propellants results in substantial increases in the theoretical specific impulse. There are several surveys investigating the potential benefits of beryllium addition to rocket propellants, mostly solid rocket propellants. Applications of beryllium in solid propellants will be discussed in more detail in future volumes on solid propellants. Applications of beryllium powder as a slurry suspended in liquid propellant fuels will be discussed in more detail in the future volume on non-hypergolic bipropellant combinations.

## 4 Magnesium Metal

Magnesium is used mostly in pyrotechnic formulations and not so much in rocket propellants. The main application of magnesium is in military illumination and signaling flares and in display fireworks. The use of flash powder for photography is part of a bygone era, but it saw a lot of magnesium powder burned to create some light for family portraits or newspaper reporting. The photographer held a pan covered with magnesium chips on a broomstick and lit it with a long fuse. People had to sit or stand still while the fuse burned. That is history.

Magnesium has been evaluated as a slurry in kerosene fuels in combination with liquid oxygen (LOX) and storable oxidizers. It has no advantage over aluminum, which is more widely used for the same purpose. Finely powdered spherical magnesium can be prepared by evaporating magnesium in a stream of helium and flash cooling it in a vertical tower [82]. Similar methods can be used for the preparation of other finely divided metal powders.

## 5 Aluminum Metal

Aluminum, Al, aluminium, CAS RN [7429-90-5], is the second most abundant metal in the universe after iron. By mass, aluminum makes up about 8% of the Earth's crust. It is the third most abundant element after oxygen and silicon and the most abundant metal in the crust, although it is less common in the mantle below. Aluminum metal

is so chemically reactive that it occurs only very rarely as native metal in the metallic state in nature. Instead, it forms part of over 270 different minerals, mostly mixed oxides. The main mineral from which aluminum is made is bauxite.

Pure aluminum is relatively soft and weak, but it forms many strong alloys. It has high thermal and electrical conductivity. Aluminum's adherent passivating surface oxide film makes it corrosion resistant. It resists attack by most acids, but alkaline solutions dissolve the oxide film and cause rapid corrosion.

The current section deals only with the physical and chemical properties of aluminum. There are several other chapters in this book that deal with specific applications of aluminum as fuel in solid and liquid rocket propellants. A future set in an encyclopedia of solid propellants will deal with aluminum in solid propellants, also combustion of nanomaterials, including nanoaluminum in various oxidizing environments. In the area of liquid propellants, kerosols are gelled suspensions of aluminum in kerosene and these have been tested extensively ever since 1933 in combination with LOX and other oxidizers.

The performance of many explosives can be enhanced by adding a few percent aluminum powder. Aluminum/air dust explosions are used in thermobaric explosives. Summaries of all kinds of properties of aluminum and its reactivity are published in [83, 84].

## 5.1 Production of Aluminum Metal

The production of aluminum metal by electrolysis of molten potassium hexafluoroaluminate (cryolite) is a well-established industry. The small percentage of aluminum used as rocket propellant has no significant impact on the availability of aluminum.

### 5.1.1 Production of Aluminum Powder

Most of the aluminum powder is used as pigment in paint ("silver" paint) in the form of flakes that have good light reflecting properties. A small portion is used in thermites for pyrotechnic incendiary and thermite iron-welding applications. For rocket propellant and explosive applications, spherical as opposed to flake-shaped particles are preferred. Prior to the advent of nanoaluminum, micron-size spherical aluminum powders were produced by a vapor condensation process. Suppliers for micron-size ("atomized") spherical aluminum powders include(d) Valley Metallurgical Processing Company (Haskell, NJ) and Argonide (Sanford, FL). Micron-sized H-5 aluminum may be passivated by treatment with potassium dichromate.

Valley Metallurgical H-3 (3 micron), and Alcan MDX-65 (6 micron) spherical aluminum powders have been produced by Valley Metallurgical Processing Company and can be used for rocket propellants.

Nanoaluminum can be made by the process of electro-explosion of metal wires, which was first developed in Russia in 1975 for the production of nanometer-sized metal powder (See section “Production of Nanoaluminum”). One of the brand names for nanoaluminum made by this process is Alex<sup>®</sup>. Particles of Alex<sup>®</sup> are typically spherical with diameters in the range of 100–200 nm and Brunauer–Emmett–Teller (BET) surface areas of 12 m<sup>2</sup>/g. For the first several years, Alex<sup>®</sup> was produced in Russia and sourced out by Argonide Corporation.

### 5.1.2 Particle Size of Aluminum

The particle size of aluminum powder is an important criterion that will affect the burning rate of solid propellants. The particle size of nanoaluminum may change with time due to agglomeration of small particles.

Thermogravimetric analysis (TGA) was used to study the reactivity of aluminum powders in air, oxygen, and nitrogen. In addition, the data were to characterize active Al content, Al oxide content, volatile impurity content, particle size, and particle size distribution [85]. Weight gains from complete oxidation of the Al were used to calculate average particle sizes in the range of 30–500 nm. These particle sizes correlated well with particle sizes derived from surface area measurements. Particle size was also examined by SEM and compared with crystallite size determined by X-ray diffraction (XRD). Particle size distributions were derived from TGA analysis data based on a model for uniform oxidation of Al from the exterior to the interior of the particle. The method is well-suited for analyzing samples with broad particle size distributions, and in particular, for monitoring the presence of 500–5000 nm particles within nominally nanosized samples. Nitridation of Al powders was studied for extended times at 873 K (600 °C). Surprisingly, 2 μm powder was nearly completely nitrided in 1 h, indicating that the nitride coating has little inhibiting effect on the reaction.

## 5.2 Physical Properties of Aluminum

The heat of combustion of aluminum is 7420 cal/g. Physical properties of aluminum are summarized in Table 6.

### 5.2.1 Vapor Pressure of Aluminum

The vapor pressure of molten aluminum in the temperature range 1557–2329 K can be calculated from an Antoine equation

$$\log_{10}(P) = 5.73623 - [13204.109 / (T - 24.306)]$$

where  $P$  is the vapor pressure in bar and  $T$  is the temperature in K. The enthalpy of formation of aluminum vapor at 298 K is  $330.0 \pm 4.0$  kJ/mol. The enthalpy of formation of liquid aluminum is 10.56 kJ/mol.

**Table 6:** Physical properties of aluminum.

| Property                         | SI Units                                | Other units                               |
|----------------------------------|-----------------------------------------|-------------------------------------------|
| Atomic mass                      | 26.9815386 g/g-atom                     | 37.0623 g-atom/kg                         |
| Melting point                    | 933.45 K                                | 660.3 °C                                  |
| Boiling point                    | 2793 K                                  | 2520 °C                                   |
| Density at 293 K                 | 2.6989 g/cm <sup>3</sup>                | —                                         |
| Heat capacity at 298 K           | 0.90 J g <sup>-1</sup> K <sup>-1</sup>  | 0.21 cal g <sup>-1</sup> °C <sup>-1</sup> |
| Heat of fusion at 933 K = 660 °C | 10.56 kJ/g-atom                         | 2.56 kcal/g-atom = 94.5 cal/g             |
| Heat of sublimation              | 326 kJ/g-atom                           | 78.0 kcal/g-atom                          |
| Heat of combustion               | 837 kJ/g-atom                           | 200 kcal/g-atom                           |
| Thermal conductivity at 300 K    | 2.47 W cm <sup>-1</sup> K <sup>-1</sup> | —                                         |

### 5.2.2 Heat Capacity of Aluminum

The solid, liquid and gas phase heat capacities of aluminum as a function of temperature can be calculated from the following polynomial Shomate equation:

$$C_p^\circ = A + B \times \tau + C \times \tau^2 + D \times \tau^3 + E/\tau^2$$

where  $C_p$  is the molar heat capacity in J mol<sup>-1</sup> K<sup>-1</sup>,  $\tau$  is the temperature in kelvin divided by 1000 and A, B, C, D, and E are constants listed in Table 7 for three different temperature ranges.

**Table 7:** Thermodynamic property polynomial equation coefficients for aluminum.

| Physical state       | Solid     | Liquid                     | Gas       |
|----------------------|-----------|----------------------------|-----------|
| Temperature range, K | 298–933   | 933–2790                   | 2790–6000 |
| A                    | 28.08920  | 31.75104                   | 20.37692  |
| B                    | –5.414849 | $3.935826 \times 10^{-8}$  | 0.660817  |
| C                    | 8.560423  | $-1.786515 \times 10^{-8}$ | –0.313631 |
| D                    | 3.427370  | $2.694171 \times 10^{-9}$  | 0.045106  |
| E                    | –0.277375 | $5.480037 \times 10^{-9}$  | 0.078173  |

## 5.3 Chemical Properties of Aluminum

### 5.3.1 Reactions of Aluminum

Aluminum is a very reactive metal and that is why it is used as an ingredient in rocket propellants. The main reaction we are concerned with here is the oxidation of aluminum by oxidizers leading to ignition and combustion. The reactivity depends on the particle size and possible passivating coatings of the particles. Coarse aluminum has to melt before it can burn. It is well known that aluminum will corrode rapidly

in alkaline solutions but will resist many acidic environments. The reaction of aluminum with sodium hydroxide solutions, a popular method for making hydrogen gas, will have active atomic hydrogen at its surface, that under certain conditions can temporarily form a thin layer of aluminum hydride [86]. It was concluded that  $\text{AlH}_3$  forms continuously during dissolution by reaction of cathodically generated hydrogen with the Al metal and is oxidized to aluminate ions in the accompanying anodic process.

### 5.3.2 Ignition of Aluminum Powders in Air

Aluminum powders, in particular nanoaluminum powders, may ignite spontaneously in air under unfavorable conditions (moisture, electrostatic sparks). Before studying the ignition of aluminum particles in air, the particle size had to be known. A comparison of different experimental techniques for metallic particle size evaluation including light diffraction, scanning electron microscope analysis and nitrogen adsorption was made in preparation of ignition tests, including nitrogen adsorption method for particle size evaluation. Chemical reactivity of micron and submicron aluminum powders in air was measured using TGA/DTA [87]. Three types of Al powders were analyzed: S-400 (Reynolds Co.), Alex (Argonide Corp.), and WARP-1 (Ceramic and Materials Processing, Inc.). Based on TGA/DTA analysis, S-400 (specific surface area =  $0.3 \text{ m}^2/\text{g}$ ) did not react below the melting point of Al (2% conversion). Alex powder (specific surface area =  $12.0 \text{ m}^2/\text{g}$ ) started reacting at around 713 K ( $440^\circ\text{C}$ ) and 16% had reacted before the melting point temperature was reached. WARP-1 samples (specific surface area between 16.0 and  $26.5 \text{ m}^2/\text{g}$ ) already reacted at 473 K ( $200^\circ\text{C}$ ) and 25 mass-% of aluminum was oxidized below melting point temperature. Differential thermal analysis did not discover any “stored” energy in S-400 or Alex materials; however, WARP-1 samples released thermal energy already at 403 and 503 K ( $130$  and  $230^\circ\text{C}$ ), which was assigned to “stored energy.”

The minimum ignition temperature of aluminum dust clouds was investigated in a heated furnace and compared to predictions from a theoretical model of aluminium dust cloud ignition in the hot zone of a heated furnace [88]. The model was developed based on two-phase flow, heat transfer, and chemical reaction kinetics. The kinetic parameters of  $E_a$  and A in the model were calculated from the dependence of ignition delay on temperature. The theoretical model could predict the minimum ignition temperature under different conditions exceptionally well.

Minimum ignition temperatures and explosion characteristics of micron-sized aluminum powders were examined in a 20-L near-spherical dust explosion chamber with different ignition energies, dust particle sizes, and dust cloud concentration values [89]. It was found that under similar dust-cloud concentrations and with dust particle size increasing from 42.89 to  $141.70 \mu\text{m}$ , the minimum ignition temperatures of aluminum powder also increased.

### 5.3.3 Specifications for Aluminum

The procurement of aluminum powder is covered by the following MIL-SPECs:

- MIL-A-512 and amendments 1-4, Military Specification: Aluminum Powder, Flaked, Grained, and Atomized (20 May 1961) [Superseding JAN-A-289] [S/S by MIL-DTL-512B]
- MIL-A-23950A, Military Specification: Aluminum Powder, Spherical (1-Sep-1966) [S/S by MIL-PRF-23905B]; MIL-A-23950A (1966) shows three different grades of spherical aluminum powders.
- MIL-A-81335, Aluminum Powder, Spherical (8-Nov-1965) [No S/S document]
- JAN-A-667, National Military Establishment Specification: Aluminum Powder, Superfine (20-Aug-1948)

### 5.3.4 Analysis of Aluminum

The analysis of aluminum in propellant mixtures is a fairly easy process and there are many methods available. The main step is sample preparation to make sure the sample is no longer combustible or explosive while it is digested to extract the aluminum and convert it to a water-soluble form. Another important analytical method would be to determine the amount of unburnt aluminum in propellant exhaust because aluminum particles do not always burn to completion this is a waste of energy that could have been used to deliver propulsion.

A permanganatometric variant of the titrimetric method was found to be suitable for measuring metallic/unburned aluminum in propellant or exhaust [90]. The determination of aluminum nitride in combustion products using a combination of wet chemical and XRD methods was illustrated by results obtained from condensed combustion products of propellant formulations containing highly active ultrafine aluminum powder. Even for this formulation the content of aluminum nitride in the final condensed combustion products was found to be negligibly small, independently of the nature of the gas (argon or nitrogen) used for bomb pressurization.

## 6 Nanoaluminum

Much to-do has been made about nanometals and their potential for increasing the performance of propellants and explosives. Since this is only a change of physical properties and has little to do with chemistry, we have not attempted to keep track of the many publications on nanometals and other nanomaterials. Just a few publications are referenced here to serve as a superficial sampling of the type of information that is available in the literature. Nanoaluminum has unique properties and has been extensively evaluated as a rocket propellant ingredient but no commercial flight applications are known [91–94].

Different conditions of nanoaluminum synthesis by the exploding wire method and powder passivation were used to optimize the process: syntheses under low-pressure gases (Ar, N<sub>2</sub>, CO<sub>2</sub>) and passivation in atmospheric pressure gases (air, N<sub>2</sub>, CO<sub>2</sub>) [95, 96]. Particle sizes and morphology were measured with a transmission electron microscope (TEM). Particle shapes were predominately spherical. The specific surface area determined by the BET method was 15–40 m<sup>2</sup>/g. The composition and surface properties of nanopowders produced under various conditions were studied by mass-spectroscopy.

Nanoaluminum can be made by the process of electro-explosion of metal wires, which was first developed in Russia in 1975 for the production of nanometer-sized metal powder. One particular brand of nanoaluminum is known under the trade name Alex<sup>®</sup> manufactured by the exploding wire method. Particles of Alex<sup>®</sup> are typically spherical with diameters in the range of 100–200 nm and BET surface areas of 12 m<sup>2</sup>/g. For the first several years, Alex<sup>®</sup> was initially produced in Russia and sourced out by Argonide Corporation.

When conducting literature searches for nanoaluminum, it is advisable to search for both spellings: in one word and in two words as nano aluminum and also connected by a hyphen. It appears that the two-word spelling is more popular in the literature, but we preferred the one-word spelling for the document at hand. In addition, the European spelling of aluminium needs to be included in the search. Nanoaluminum may also be called “activated aluminum.” A popular abbreviation is nAl.

## 6.1 Production of Nanoaluminum

Nanometals like nanoaluminum are produced by electro-explosion (plasma-explosion process) of metal wires in an inert gas atmosphere at 2–3 atm pressure [97–99]. The electrical discharge instantly vaporizes the metal, briefly maintains a plasma of metal vapor which is then carried away by the purge gas. The metal vapor condenses in the form of nanometer-size metal particles of about 50–100 nm in diameter. The nanometal is separated from the purge gas in a cyclone separator or a sedimentation chamber and stored under an inert hydrocarbon oil or under argon. Once passivated in dry air, the high surface area powder contains 5–8% of adsorbed air. A similar process heats and vaporizes the metal by a pulsed laser instead of a plasma discharge. Al nanopowders with diameters ranging from 20 to 50 nm can also be produced by two different evaporation routes: induction heating evaporation (IHE) and laser-induction complex heating evaporation (LCHE).

Several production processing parameters affect the physical, thermal and combustion properties of plasma-synthesized aluminum nanopowders [100, 101]. It was shown that feed rate and quench rate had the largest effect on particle size. All synthesized powders were characterized by TGA/DTA, field emission SEM, BET surface area, and bomb calorimetry.

Another mechanical process for comminuting metal particles is ball milling of aluminum in gaseous atmospheres of ammonia and monomethylamine (MMA) which can produce particles in the 100 nm size range [102]. A combination of mass spectrometry, X-ray photoelectron spectroscopy (XPS), thermogravimetric analysis with mass spectrometric product analysis (TGA-MS), SEM, IR spectroscopy, and dynamic light scattering (DLS) was used to study the particles and the chemical interactions responsible for particle production. Both  $\text{NH}_3$  and MMA react with aluminum under milling conditions, producing  $\text{H}_2$  and other gaseous products, and leaving the surfaces functionalized. The surface functionalization enhances size reduction by reducing the surface free energy and the tendency toward mechanochemical coalescence. For both  $\text{NH}_3$  and MMA, the particle cores are metallic aluminum, but the surface chemical properties are quite different. The ammonia-milled particles are coated by an  $\text{AlN}_x\text{O}_y\text{H}_z$  layer ~10 nm thick, which passivates the particles. The MMA-milled particles are coated with a thinner passivating layer, such that they are pyrophoric in air and react with  $\text{N}_2$  at elevated temperatures. A similar process used either vapor-phase or liquid-phase acetonitrile as the ball-milling fluid [103]. The Materials Research Society which conducts periodic symposia on energetic materials, has devoted an entire conference series to the discussion of the synthesis, characterization and properties of energetic/reactive nanomaterials [104].

A mathematical model of nanoparticles formation by condensation from the vapor phase process was developed and applied to the manufacture of alumina-coated aluminum nanoparticles [105]. This process involves conversion of gaseous aluminum in the presence of helium carrier gas to solid aluminum nanoparticles. The mathematical model is useful to study the trends on the dependence of the nanoparticle size distribution on the operating parameters such as pressure and temperature profile in the reactor.

Nanoaluminum particles can form by the corrosive attack of caustic solutions on aluminum foil [106]. The as-prepared aluminum particles were composed of several aluminum microcrystals. Their size depends on the concentration of  $\text{OH}^-$  in the caustic solution. See also [107].

## 6.2 Protective Coatings for Nanoaluminum

Instead of using the term “coated nanoaluminum,” sometimes researchers also use the term “capped nanoaluminum.” Encapsulation also describes the coating process. Using all three terms in a literature search may improve the results of the search.

Nanosize aluminum (Alex<sup>®</sup>), an organic coated variant (L-Alex<sup>®</sup>), and a 17  $\mu\text{m}$  aluminum powder (Cap45a) were aged under accelerated conditions of elevated temperature and humidity [108]. Fourier transform infrared (FTIR) and mass spectrometry analyses identified the passivation coating on L-Alex as palmitic acid and showed it to be chemically bound to the aluminum surface via a carboxylate linkage. This coat-

ing was shown to form an effective barrier to hydrolysis and oxidation, with only minor degradation of the metal seen after 40 days of accelerated aging. The coating was retained on the metal surface and provided excellent protection against oxidation.

Nanoaluminum particles are covered by an amorphous oxide layer, which is typically 0.5–4 nm thick. For example, a 38-nm diameter aluminum particle has ~47.5 mass-% oxide which detracts from its value as a rocket fuel. The specific thickness of the oxide layer depends on the temperature of the particle and the duration of exposure to the oxidizing environment. When the particle is exposed to the oxidizing gas for a sufficient period, the oxide layer thickness saturates at a value of 4 nm<sup>3</sup>. The oxide layer protects the particle from further attack by the oxidizer. Aluminum particles with diameters greater than 100  $\mu\text{m}$  ignite only upon melting of the oxide layer at 2350 K. This results in a long ignition delay and a slow rate of energy release. It is thus desirable to reduce the ignition temperature of micrometer-sized aluminum particles. The formation of the oxide layer on aluminum particles can be significantly inhibited by applying transition metal coatings which have higher melting points than the aluminum.

A considerable amount of effort has been directed towards making nanomaterials safer and easier to handle. One approach toward achieving this goal is to passivate the nanomaterials by functionalizing their surfaces. The disadvantage of nanoaluminum is that if it is kept in air, it will be covered by a thick oxide layer, which reduces its energy content. This happens if it is not passivated sufficiently to prevent further oxidation during storage. The kinetics of the interaction of Al nanopowders with N<sub>2</sub>, air, and moisture were investigated by DTA-TGA and by volumetric analysis [109]. If nanopowders are coated with passivating agents, they often retain large amounts of solvents from which the coating was precipitated. Organic coatings (oleic acid) protect the surface against further oxidation more effectively than oxide coatings. The surface of electro-exploded aluminum nanopowders can be passivated by nitrocellulose, oleic acid (C<sub>17</sub>H<sub>33</sub>COOH) and stearic acid (C<sub>17</sub>H<sub>35</sub>COOH), suspended in kerosene and ethanol [110–112].

Coated and uncoated nanoaluminum can react with nitrogen and become nitrated at higher temperatures [113]. Aluminum nanopowders with a protected surface had increased stability to oxidation in air during storage and higher reactivity by heating [114].

Coating nanoaluminum with hydroxyl-terminated polybutadiene (HTPB) would serve two purposes: it would protect the metal particles from oxidation and it would improve the bonding between particles and HTPB binder in a solid propellant formulation [115]. The reactivity and 2-year storage stability of HTPB-coated Al nanopowders outperformed Al<sub>2</sub>O<sub>3</sub>-passivated Al nanopowders.

Fluorocarbon polymer powders added to monopropellants containing aluminum are known to improve burning rates and achieve more complete combustion of aluminum. The same mechanism helps to improve burning rates and protection against air oxidation of nanoaluminum coated with fluorocarboxylic acid functional coatings

[116]. The fluorocarboxylic acid functional coating was 1–2 nm thick, and TGA analysis confirmed an 80% active fuel content, an increase of 17% from untreated product.

Protective coatings evaluated for nanoaluminum include nickel [117], carbon [118–122], cyclooctane [123–125], polystyrene [126, 127], fluorocarbon polymers and long-chained perfluorinated carboxylic acids [128–130], and other coating materials [131]. Carbon-coated nanoaluminum is more resistant to moisture than uncoated nanoaluminum [132].

Coating nanoaluminum with HTPB improved storability, processability of formulations prepared with nano-Al and adhesion to binders in composite solid propellants [133]. Gaseous, liquid, and solid passivating reagents were investigated [134]. The advantages of non-oxide passivation are the potentially higher combustion heat of the powders covered by organic passivating layers and a lower particle size for such aluminum nanopowders in comparison with the commercially produced powder Alex<sup>®</sup>.

Nanoaluminum coated with hydrocarbons or fluorocarbons is more resistant to oxidation in air than uncoated nanoaluminum [135]. It was found that while fatty acids have a weak effect on the non-isothermal oxidation behavior, fluoroelastomers shift the oxidation onset of nanoaluminum to higher temperatures by ~20 °C for the first oxidation stage and by ~100 °C for the second oxidation stage.

The reactivity of passivated aluminum nanopowders was studied and it was shown that organic coatings enhance the resistance of aluminum nanoparticles to the effect of water vapor and cause changes in the parameters of the non-isothermal oxidation by air oxygen [136]. Passivation of aluminum nanopowders has been established to increase the temperature of oxidation onset and the heat release rate.

Nanoaluminum was modified with three different functional organic silanes and the effect of organic coatings on reducing oxidation of n-Al was measured via accelerated aging tests [137]. This study showed that all three types of organosilane-modified nanoaluminum have much better resistance to aging than the pristine uncoated nanoaluminum. See also [138, 139].

### 6.3 Physical Properties of Nanoaluminum

Pressed pellets of nanoaluminum had an unusually high electrical resistance, indicating that the particles are surrounded by an oxide layer which may behave like a semiconductor with electron defect conduction. Scanning electron microscope images showed the nanoparticles to change shape and coalesce into spheres if the electron beam energy was too high, a sort of unintentional electron beam welding.

In order to obtain more reproducible results with different batches of nanoaluminum, the nanoparticles need to be better characterized. A variety of standard particle characterization techniques were applied to 15 different types of particles [140]. The parameters measured were average particle diameter, specific surface area, amount of active content, and oxide layer thickness. Trends in propulsion performance measured

using a parameter of great interest to the hybrid rocket community (fuel mass burning rate) in general matched trends in particle characteristics (i.e. active content, surface area), but there were some noticeable exceptions. Other parameters that need to be examined include particle size distribution, degree of agglomeration, reactivity and thermal effects. See also [141].

### 6.3.1 Melting Behavior of Nanoaluminum

Nanocrystalline aluminum powders have been synthesized by mechanical attrition under different atmospheres or by gas condensation. The crystal refinement and the development of the microstructure were investigated by XRD, DSC, TEM, and electron energy loss spectrometry. Both preparation techniques lead to powders with comparable grain sizes. There is a drastic reduction of the melting point with decreasing grain size, in comparison to the bulk melting point value [142]. Subsequent remelting does not recover the bulk melting point. This is due to the microstructure of the nanocrystalline powders, the contribution of the stored enthalpy of cold work, and the nucleation of disorder/melting at grain boundaries/particle interfaces.

A nanocomposite material has been prepared by consolidation of gas-phase condensation nanocrystalline aluminum particles, which had been passivated with an alumina overlayer prior to the compaction step and it was characterized by XPS, DSC, TEM, and atomic force microscopy (AFM) [143]. The consolidated material, although showing a metallic shine and an ohmic electrical resistivity, presents a microstructure constituted of Al grains interconnected by a very thin alumina network, which prevents the material from falling apart when heated at temperatures above the melting point of aluminum.

The melting point of nanoaluminum decreased with decreasing particle size and the heat of fusion decreased. The effect of the oxide coating on the particles is to apply a compressive force to the aluminum core, thereby increasing the observed melting point and the heat of fusion. The melting point depression, both corrected and uncorrected for the effects of the oxide shell, is linear with the reciprocal of particle radius [144]. The size-dependent heat of fusion was significantly smaller than that predicted by the effects of the surface tension indicating that the solid nanoparticle is at a higher energy than expected, presumably due to the presence of defects or irregularities in the crystal structure at or emanating from the surface.

### 6.3.2 “Stored Energy” in Nanoaluminum?

The process of electro-explosion of metal wires, which has been known for more than 200 years, has been adapted to the preparation of activated aluminum, called Alex. The process produces metallic particles of approximately 50–100 nanometers in size. The most unusual characteristic of this aluminum is the “stored energy” that is released upon reaching a threshold temperature. While this heat generation has been confirmed by other researchers, no one has a proven theory for the source of this en-

ergy. It was postulated that during the very rapid cooling of an individual droplet of aluminum, the outer region of the particle would cool faster than the inner region and if an outer shell solidifies and shrinks as it cools, it may compress the molten liquid in the inner region. This process may work on the liquid region and store energy in the particle [145, 146].

A critical re-evaluation of stored energy in ultrafine aluminum powder produced by plasma explosion concluded that the postulated stored energy mechanism results in measurable stored energy for only unrealistically high cooling rates [147]. The objective of this study was to determine whether measurable energy can in fact be stored in an Alex particle during the rapid solidification process because of the compression of the inner liquid region by the shrinking outer solid shell or crust. It was concluded that although the postulated mechanism could store energy, the amount of energy stored is negligible. This theoretical finding was in agreement with experiments that showed no observable stored energy in Alex particles.

Mixtures of Alex with various oxidizers yielded burning rates many times higher than those of mixtures with ordinary aluminum powder. This enhanced burning rate phenomenon of Alex was confirmed for several solid propellants with hydroxyl-terminated polybutadiene (HTPB) as the binder [148].

However, the cause for this burning rate increase has not yet been definitively identified. Using TGA and DTA of Alex, Ivanov and Tepper noted that an exotherm occurred at 723 K (450 °C) and peaked at 823 K (550 °C) in the absence of air, without oxidation. From this result, it was suggested that the unique burning characteristics of Alex might be due to a stored internal energy, which is released on reaching a threshold temperature. Ivanov estimated this stored energy to be 400 cal/g (or  $1.67 \times 10^6$  J/kg). This claim of stored energy has been refuted by several research teams. TGA and DTA experiments with Alex, observed no release of internal energy [149]. Laboratory experiments using DSC and DTA arrived at the same conclusion [150, 151].

Before the publication of these findings, a study commenced with the intent of investigating the possibility that the rapid solidification of aluminum droplets during the plasma explosion process might impart stored internal energy to Alex showed that, in principle, a highly disordered crystal may contain higher internal energy than the same material in a more ordered crystal structure. Therefore, the recrystallization process could be exothermic. According to Ivanov and Tepper, the energy released by recrystallization is too small to produce the unique behavior of Alex, and an alternative source of internal stored energy was considered.

### 6.3.3 Crystal Structure of Nanoaluminum

Aluminum nanopowders with diameters ranging from 20 to 50 nm passivated by Al<sub>2</sub>O<sub>3</sub> coatings can be produced by two different evaporation routes: Induction heating evaporation (IHE) and laser-induction complex heating evaporation (LCHE). Thermal and crystal structure properties of these nanopowders were investigated

by DTA in a dry oxygen environment [152]. The results showed that Al nanopowders produced by LCHE had an oxidation enthalpy change ( $\Delta H$ ) of 3.54 kJ/g, while the  $\Delta H$  of Al produced by IHE was only 1.18 kJ/g. The phase constitution and microstructures of these nanopowders were revealed using XRD, TEM, and high-resolution transmission electronic microscopy (HRTEM). The results showed that the two powders had the same composition and mean particle size, as well as the same thickness of  $\text{Al}_2\text{O}_3$  coatings (3–5 nm). Defects were observed on the surfaces of the particles by LCHE; however, the defects were not detected by HRTEM on the surfaces of the particles by IHE. The results indicated that there exists excessive stored energy in Al nanopowders by LCHE because of the non-equilibrium condition brought by the laser and the defects are the storage location of the excessive stored strain energy. Propellants containing Al nanopowders made by LCHE showed higher specific impulse than those made by IHE.

## 6.4 Chemical Properties of Nanoaluminum

Many nanometals in the freshly prepared state are pyrophoric and have to be handled under an inert atmosphere to prevent autoignition. Some may even autoignite with nitrogen. Passivated nanoaluminum has very sharp exotherms when heated in oxygen or nitrogen. The exotherm starts well below the melting point of Al, while coarse, micron-size Al does not ignite in air until about 1273 K (1000 °C). The metals can be passivated by slow controlled exposure to dry oxygen in an argon atmosphere and can be protected by a hydrophobic coating (e.g. palmitic acid) or a water-impervious plastic film (polytetrafluoroethylene). In passivated and coated nanoaluminum the useful Al content is only 88–90 mass-%. If a layer of nanoaluminum powder is spread on a ceramic plate and ignited, a dark-glow exothermic reaction propagates through the powder before it ignites. The process of self-heating and self-sintering of the powder is faster than the oxidation reaction [145]. When one edge of a pressed pellet of nanoaluminum is pressed against a hot plate, there is a visible light-emitting hot zone traveling through the pellet. The source of this stored energy has not yet been totally explained.

### 6.4.1 Reactions of Nanoaluminum

There is concern that nanoaluminum particles may sinter together and coalesce during storage and they may have only a limited shelf life. The activities of different aluminum powders were studied by means of a gasometric method [153]. The results showed that the activity of spherical nanoaluminum powder is 76.1%, and the activity of common flake aluminum powder is 43.0%. Particle sizes had significant effects on the activities of aluminum powders. The shelf life prediction of nanoaluminum was studied by an accelerated test and a Berthelot method. If one assumes that the co-

alescence change values of nanoaluminum powder are 10, 20 or 30% as expiration limits, then the shelf lives of nanoaluminum powder are predicted to be 4.73, 9.77, and 14.80 years at 298 K (25 °C).

With its large surface area, nanoaluminum can adsorb many species, some adversely affecting its stability, others providing a protective coating. The composition of adsorbed species can be determined by temperature-programmed desorption with mass spectrometric analysis of the off-gassing. Water adsorption and desorption is a particular concern, since the aging reaction of Al nanopowders may be related to the water adsorbed on its surface. The thermodesorption of adsorbed gases on nanometer-sized aluminum powders was investigated using TGA and TGA-FTIR-MS [154]. The results showed that the Al nanopowder studied contained 12 mass-% of adsorbed gases. Desorption of water and carbon dioxide was observed by FTIR and MS. The kinetic parameters for the desorption of the adsorbed gases were determined using variable heating rate and isothermal studies giving numbers for the activation energies of desorption.

#### 6.4.1.1 Reactions of Nanoaluminum with Liquid Water

Nanoaluminum reacts rapidly with water:

The reaction begins at 323 K (50 °C) and accelerates to explosive strength at 353 K (80 °C) [155]. A gelled propellant consisting of Alex in cold water gelled with 3% polyacrylamide is stable for only a short time. Its burning rate in 1 cm diameter × 3 cm length quartz tubes in an argon-filled Crawford bomb was measured as a function of pressure and the burning rate can be expressed by the equation

$$r = 0.183(P/P_0)^{0.4}$$

where  $r$  is the linear burning rate in cm/s,  $P$  is the pressure in atm and  $P_0$  is the pressure of 1 atm [146]. Nanoaluminum ignited by a hot wire in a nitrogen-filled Crawford bomb burned vigorously at 20–60 atm, forming AlN containing a little (3%) unreacted Al. Mixtures of nanoaluminum with lead nitrate or barium nitrate and ignited by a hot wire under heavy confinement formed AlN instead of  $\text{Al}_2\text{O}_3$ . It appears that under the conditions of this experiment, the formation of AlN is favored over the formation of  $\text{Al}_2\text{O}_3$ , contrary to what thermodynamics would predict.

A suspension of nanoAl/gelled water slurry was prepared by adding 0.1 mass-% polyacrylamide and mixed with 15 mass-% nanoAl powder (mean particle size 50 nm) [156]. The single droplets were suspended on the tip of a quartz fiber and ignited using a hot nichrome wire or an electric arc in air or argon atmosphere. The experiments showed that the droplets can ignite and burn in air or argon with a stable spherical flame. Successful experiments in the inert atmosphere confirmed that the combustion occurs due to the reactions between Al and  $\text{H}_2\text{O}$ . Replacement of nanoAl with coarser

Al powder (6  $\mu\text{m}$ ) dramatically increased the ignition delay time in air and made the ignition in argon impossible.

In a study of the self-deflagration of nanoAl and liquid water without the use of any additional gelling agents, steady-state burning rates were obtained at room temperature using a windowed chamber for a pressure range of 0.1–4.2 MPa in an argon atmosphere, particle diameters of 38–130 nm, and overall mixture equivalence ratios ( $\phi$ ) from 0.5 to 1.25 [157, 158]. At the highest pressure studied, the linear burning rate was found to be  $8.6 \pm 0.4 \text{ cm/s}$ , corresponding to a mass-burning rate per unit area of  $6.1 \text{ g cm}^{-2} \text{ s}^{-1}$ . The pressure exponent at room temperature was 0.47, which was independent of the overall mixture equivalence ratio for all of the cases considered. The mass-burning rate per unit area increased from  $\sim 1.0$  to  $5.8 \text{ g cm}^{-2} \text{ s}^{-1}$  for an equivalence ratio range of  $\phi = 0.5$ –1.25. It varied inversely to particle diameter, increasing by 157% when the particle diameter was decreased from 130 to 50 nm at  $\phi = 1.0$ .

The suspensions of aluminum in water would have to be gelled to prevent settling of the particles during standing [159, 160]. Using liquid hydrogen peroxide in place of water would give even more energetic propellants [161–163].

The reaction of suspensions of nanoaluminum in liquid or frozen water can be discussed here in the chapter on reactions of metals or in future volumes on mono-propellants, gelled propellants, and solid propellants. Some of the more academic studies, short of actually launching a rocket with these propellants, are already described here in the current and the following section. There may be some overlap of the information presented in different volumes.

The reaction of nanoaluminum with water for the production of hydrogen can be initiated by a trace of LiOH and the hydrogen gas can be used in fuel cells or other devices [164].

The strand-burning rate of nanoaluminum/water mixtures was studied for particles in the size range of 38–130 nm and over a pressure range of 1–10 MPa in a constant volume high-pressure chamber [165]. The burning rate as a function of pressure and particle size could be expressed by the equation

$$r_b = 98.8P^{0.32}d_p^{-1}$$

where  $r_b$  is the burning rate in cm/s,  $P$  is the pressure in MPa and  $d_p$  is the particle diameter in nm. The flame zone thickness increased with increasing particle size and decreasing pressure. The rate of combustion of aluminum/water mixtures was controlled by mass diffusion across the inevitable oxide layers coating the particles.

#### 6.4.1.2 Reactions of Nanoaluminum with Frozen Water

The theoretical specific impulse of the Al/H<sub>2</sub>O propellant is about 300 s. The propellant combination of aluminum and ice (frozen water) has become known under the name *Allce*. Similar combinations have been called *refrigerated solid propellants* or *cryogenic solid propellants*. Allce propellants are simple to prepare, water is likely to

be found near extraterrestrial landing sites, and Allce propellants are good candidates for propulsion using **In-Situ Resource Utilization (ISRU)** methods. A rocket propellant has been tested consisting of nanoaluminum embedded in a matrix of frozen water. This cryopropellant must be kept below freezing all the time [166].

Nanometer sized aluminum particles, when combined with water to self-propagate, reacted to form high-temperature molecular hydrogen and condensed phase aluminum oxide. Freezing these mixtures produced a storable solid propellant having potential applications to hydrogen storage. Generally, the particles used had a nominal diameter of 80 nm and an active aluminum content of 74.5 mass-% Al. Experimental analysis of burning of frozen compositions was conducted using a constant pressure strand burner, constant volume cell and a series of scaled rocket motors [167].

The combustion of alane and aluminum powder with water in its frozen state was studied experimentally and theoretically using both nano-sized and micron-sized particles over a wide range of chamber pressures [168]. The linear strand burning rate and chemical efficiency were obtained using a constant-pressure strand burner or a constant-volume chamber, respectively. The 80-nm Al particles had spherical shapes in contrast to the rhombohedral-shaped alane. The effect of replacing nano-Al particles by micron-sized Al or alane particles was examined systematically for additive mass fractions up to 25%. The equivalence ratio was fixed at 0.943. The pressure dependence of the burning rate followed the power law,

$$r_b = aP^n$$

with  $n$  ranging from 0.41 to 0.51 for all the materials considered. For the Allce without any additive the burning rate equation was

$$r_b = 0.992P^{0.405}$$

where  $r_b$  is the burning rate in cm/s, and  $P$  is the pressure in MPa. The burning rate decreased with increasing alane concentrations, whereas it remained approximately constant with cases containing only Al particles. The chemical conversion efficiency ranged from 32 to 83%, depending on the mixture composition and pressure, too low for many of the intended applications.

The combustion of aluminum with ice was studied using various mixtures of nano-sized and micrometer-sized aluminum particles as a means to generate high-temperature hydrogen at fast rates for propulsion and power applications [169, 170]. Bimodal particle size distributions gave better mixture packing densities. The burning rate can be tailored by introducing various particle sizes. The effects of the bimodal particle size distributions and equivalence ratio on ignition, combustion rates, and combustion efficiency were investigated in strand burner experiments at constant pressure and in small laboratory scale (1.91 cm = 0.75 in. diameter) static fired rocket-motor combustion chambers with center-perforated propellant grains. The substitution of micron-size aluminum for nanometer aluminum had little effect on the linear burning rates of Allce mixtures for low-mass substitutions. The effects

of bimodal aluminum compositions on motor performance were minor, although the experimental results suggested that longer  $L^*$  chambers and combustion times are necessary for complete combustion.

Strand burning tests provided information on propellant linear and mass burning rates with respect to pressure and composition which were correlated using a Saint Roberts Law fit. Figure 1 is a comparison of linear strand burning rates of 80-nm nanoaluminum with frozen or liquid water, also using data from [171]. The black line is the result of a burning rate equation of stoichiometric ( $\phi = 1.0$ ) liquid  $H_2O/Al$

$$r_b = 1.2P^{0.27}$$

where  $r_b$  is the burning rate in cm/s and  $P$  is the pressure in MPa. In comparison, the burning rate of slightly under-oxidized ( $\phi = 0.943$ ) nanoaluminum/ice shown as the red dashed line has a burning rate equation of

$$r_b = 0.992P^{0.405}$$

where  $r_b$  is the burning rate in cm/s and  $P$  is the pressure in MPa. Graphs like Figure 1 actually belong in *Encyclopedia of Monopropellants*, but this information is shown here to illustrate the reactivity of nanoaluminum with water.

All ice mixtures were fired in strand burners and static-firing motors, instrumented with pressure and force transducers, to determine the propulsive performance of several propellant formulations. Additional formulations were tested with added ammonia borane, aluminum hydride or hydrogen peroxide. See also [161, 172–178].

**Figure 1:** Comparison of linear strand burning rates of nanoaluminum with frozen (in red) or liquid (in black) water. (Reproduced and modified from [167].)

AllIce mixtures were tested in strand burners and fired in static-firing heavy-duty motors, in preparation for a free-flight demonstration [179]. The burning rate equation for AllIce mixtures with an equivalence ratio of 0.71 was

$$r_b = 0.70274P^{0.57019}$$

where  $r_b$  is the burning rate in cm/s and  $P$  is the pressure in MPa. After several static firings in a heavy-duty motor casing, the AllIce propellant was installed in a 10-cm (4-in. O.D.), 2.5 m (8 ft 6 in.) tall sounding rocket and ignited by a solid propellant charge and launched in a free-flight demonstration. The rocket coasted upwards after the grain was depleted and reached a peak altitude of ~394 m.

Strand burning rates of aluminum/water ice (AllIce) mixtures over a pressure range of 1–10 MPa were studied using both a monomodal distribution of nanoaluminum particle sizes and a bimodal distribution of nano-sized and micron-sized aluminum particle sizes [180]. The burning rate of the 80 nm AllIce mixture increased from 1.22 to 2.5 cm/s as the pressure increased from 1 to 10 MPa. For stoichiometric AllIce mixtures with 80 nm particles, the burning rate showed a pressure dependence of

$$r_b = 1.18P^{0.33}$$

where  $r_b$  is the burning rate in cm/s and  $P$  is the pressure in MPa. If a portion of 80 nm particles was replaced with 5 and 20  $\mu\text{m}$  particles, the burning rate was not significantly affected for loading densities up to 15–25% but decreased significantly beyond this value. The pressure exponent decreased with the addition of 20  $\mu\text{m}$  Al particles. The flame thickness of a bimodal particle mixture was greater than its counterpart of a monodispersed particle mixture.

Using frozen hydrogen peroxide in place of water ice would give even more energetic propellants.

The energy and the high-pressure gases released in the aluminum-water reaction can also be used for underwater propulsion and of course there would be plenty of water surrounding the vehicle to draw from [181, 182]. A similar underwater propellant is the exothermic reaction of aluminum hydride with water [183].

#### 6.4.1.3 Oxidation of Nanoaluminum

Nanostructured aluminum is much easier oxidized than ordinary aluminum. Differential scanning calorimetry measurements showed that when heated in air, the Alex material is partly oxidized resulting in a large exotherm starting at around 723 K (450 °C) [184]. With an ordinary aluminum powder a much smaller exotherm is obtained. Microcalorimetry measurements, carried out at 338 and 318 K (65 and 45 °C), showed that Alex has good stability in dry air but that it reacts quickly, although not vigorously, at high relative humidity, releasing much heat. The BET surface area of Alex was about 12 m<sup>2</sup>/g. It was estimated that active aluminum content of micron-size aluminum is

99.5% or better, while the active aluminum content of passivated nanoaluminum typically ranges from 50 to 95%.

Experimental size-dependent reactivity measurements of aluminum nanoparticles using a single particle mass spectrometer (SPMS) indicated that the reactivity of aluminum nanoparticles increased with decreasing primary particle size as well as decreasing particle mobility size [185, 186]. A phenomenological model has been described which highlights the difference in the mechanism of oxidation of aluminum nanoparticles as compared to micron-sized particles. This model also showed the significance of physical phenomena that are important at the nanoscale, such as a pressure gradient present inside the particles, and may impact the oxidation process.

It had been suggested that very low melting temperatures should be expected for nano-sized aluminum powders and that such low melting temperatures could accelerate oxidation and trigger ignition much earlier than for regular, micron-sized aluminum powders. The melting and oxidation behavior of nano-sized aluminum powders, powder samples with three different nominal sizes of 44, 80, and 121 nm was studied by DSC where the powders were heated from room temperature to 1023 K (750 °C) in an argon environment [187]. TGA was used to measure the mass increase indicative of oxidation while the powders were heated in an oxygen-argon gas mixture. Characteristic stepwise oxidation was observed for all studied nanopowders. The observed oxidation behavior was well interpreted using published kinetics of oxidation of micron-sized aluminum powders. No correlation was found between the onset of melting and oxidation of aluminum nanopowders.

The particle structure of aluminum nanopowders oxidized at different temperatures, was modeled via geometrical considerations that enabled the calculation of the variation of specific surface area during oxidation [188]. A two-step oxidation scenario was proposed. In the early oxidation stage for temperatures up to 923 K (650 °C), where a pseudoplateau was reached, the oxidation occurred by diffusion of oxygen or aluminum through the alumina layer and resulted in a core-shell structure. At higher temperatures above the melting point of aluminum, outward diffusion of aluminum through the oxide shell was controlling the reaction rate. The reaction interface was then located at the external surface and voids were formed inside the particles. The migration of aluminum toward the surface of the particles was faster than the oxidation.

#### 6.4.2 Ignition of Nanoaluminum

Depending on the preparation history of nanoaluminum, freshly prepared, non-passivated nanoaluminum is pyrophoric in air. Aluminum particles with diameters less than about 68 nm were predicted to be pyrophoric, e.g., ignite in air without appreciable initial preheating [189, 190]. Oxidation of a nanoaluminum particle occurs in a few microseconds [191].

The oxidation and ignition of aluminum nanoparticles with a mean diameter of 150 nm was investigated with the help of simultaneous thermal analysis, XRD, EDAX, SEM, and TEM at heating rates of 2–30 K/min [192]. A unique early ignition reaction was observed when the heating rate was  $\geq 8$  K/min.

A study of the thermal and hazard properties of various uncoated and coated aluminum nanopowders and their effects on the thermal stability, out-gassing behavior and electrostatic discharge sensitivity of various energetic materials showed that these aluminum nanopowders had a mean particle size of 20–120 nm [193]. The coated samples had a layer of 7–25% of polymer. The thermal behavior of the aluminum nanopowders in air and the effects of the particle size and the coating on the reactivity of aluminum nanopowders was determined. Aluminum nanopowders are very reactive in the presence of water, resulting in aging problems. The coating with a polymer had only a minor effect on the reactivity of aluminum nanopowders with water. On the other hand, the results from an aging study showed that the coated aluminum nanopowder was more stable than the uncoated nanopowder in humid atmospheres. The addition of uncoated aluminum nanopowders has previously been shown to increase the electrostatic discharge sensitivity of both ammonium dinitramide and ammonium perchlorate to very low electrostatic ignition energies that can easily be carried by a human body. In contrast, the coated aluminum nanopowders did not appear to sensitize ammonium dinitramide and ammonium perchlorate toward electrostatic discharge, which suggested that coatings can effectively prevent the sensitization effect.

The ignition and combustion of aluminum particles of various sizes, mostly coarser than nanoaluminum, will be discussed in future volumes on solid propellants, because it affects the burning rate and performance of metallized solid propellants. That section also includes combustion of aluminum dust aerosols in air or other oxidizer atmospheres. A good review of combustion of nanoaluminum is available in [194]. Combustion of metallized liquid monopropellants containing nanoaluminum will be discussed in *Encyclopedia of Monopropellants*.

#### 6.4.3 Aging of Nanoaluminum

Small particles of any kind, not just nanoaluminum, have a tendency to agglomerate and fuse into larger particles, a process that minimizes surface area and entropy. This limits the storage life of unprocessed nanoaluminum [108]. Once formulated into solid propellants or gelled liquid propellants, the particles are separated by the continuous phase and no longer in direct contact with each other, which would prevent or delay particle growth.

## 6.5 Applications of Nanoaluminum

Besides its applications in liquid and solid rocket propellants, nanoaluminum has been evaluated as fuel in thermites used as igniters or heat sources and in explosives. These non-propulsive applications are not included in this book. Some of the studies cover a very wide range of applications, including the use of nano engineered energetic materials (NEEMs) [195]. This is a very good status report on applications of nanomaterials. See also [93, 196–202].

## 7 Metal Hydrides

Another group of rocket fuel compounds discussed here following the same sequence as the one used for getting the metals into a systematic order is the group of hydrides of these metals, in particular hydrides of light metals, such as lithium, beryllium, boron, and aluminum. These constitute quite promising rocket fuels and additives to rocket fuels. This includes simple and complex hydrides. Complex and saline hydrides combine hydrides of more than one metal in a molecule and are usually in crystalline solid form, with the exception of aluminum borohydride (aluminum boranate), which is a liquid.

Hydrides can be divided into three (four) categories, depending on the type of chemical bonds holding the hydrogen atom to its partner:

1. Covalent hydrides contain covalent bonds, such as those in hydrocarbons and hydronitrogens.
2. Saline or ionic hydrides contain hydrogen in the form of a negatively charged hydride ion  $H^-$ , such as in lithium hydride or sodium hydride. These are the types of hydrides discussed here.
3. Metallic hydrides are formed by absorption of hydrogen into the electron cloud surrounding atoms in metals. The compounds are electrical conductors and are non-stoichiometric, allowing a wide variation of hydrogen contents. Many metals become embrittled as the result of inadvertent hydrogen absorption. Reversible intermetallic hydrides such as those of iron-titanium alloys are being tested as methods for compressed hydrogen storage in vehicles. Nickel-hydrogen batteries have replaced nickel-cadmium batteries in satellites and many earth-bound applications.
4. Hydrogen bonding in diborane allows this compound to exist as a dimer of  $BH_3$ . Boranes will be discussed in the chapter “Boranes.”

The ionic hydrides are formed by the strongly electropositive alkali and alkaline earth metals. Beryllium hydride  $BeH_2$ , which is rather covalent in character, is an exception. The alkali metal hydrides are sensitive to air and humidity, and alkali metal hydride powders react violently with water. In contrast, the sensitivity of alkaline-earth metal

hydrides to air and water strongly depends on their preparation and storage. Fresh, finely divided powders may be very reactive, or even pyrophoric, but commercial  $\text{MgH}_2$  and  $\text{CaH}_2$  powders are often passivated and can then be safely handled in air.

Solid hydrides, e.g., lithium hydride, can be used as fuels in hybrid or tribrid engines. Liquid hydrides, e.g. pentaborane have been considered as liquid rocket fuels or as fuels in air-breathing engines. Boron hydrides and organic boron compounds are discussed in this book in a chapter outside the metal hydride domain because they have different hydride bonds and they have at one time assumed a more important role than all other metal hydrides combined.

Chemical rocket propellant performance can be improved by using metal hydrides that store high volumes of hydrogen at ambient conditions that can be released during combustion. A theoretical investigation of hydrides as additives in hybrid fuels and solid propellants started to look at aluminum hydride, but aluminum hydride is not commercially available. As a consequence, attention was focused on other simple and complex hydrides that are readily available [203]. A comparative analysis of theoretical mass-specific and volume-specific impulses, propellant average density, adiabatic flame features, and preliminary estimates of exhaust products was conducted. Eight different hydrides, potentially applicable as replacements for metallic aluminum currently used in solid propellants and hybrid rocket systems, were considered.

Predictive methods for calculation of enthalpies of formation of metal hydrides include Born-Haber cycles and density functional theory methods [204]. Other bibliographies and reviews on hydrides were published, such as [205]. Comprehensive reviews of metal hydrides are in [206–208]. Table 8 is a summary of physical properties of metal hydrides.

**Table 8:** Physical properties of metal hydrides.

| Hydride          | Molecular mass<br>g/mol | CAS Registry number | Hydrogen content<br>mass-% H | Density<br>g/cm <sup>3</sup> | Enthalpy of formation<br>kJ/mol |
|------------------|-------------------------|---------------------|------------------------------|------------------------------|---------------------------------|

Data source: [208]

Beryllium hydride and aluminum hydride are solids. For many rocket applications, liquid fuels would be preferred. A search was started for liquid metal hydrides with fuel performance properties similar to  $\text{BeH}_2$  or  $\text{AlH}_3$  [209]. The objectives of the liquid metal hydride research programs have been to demonstrate the feasibility of forming liquid beryllium fuels from known energetic beryllium compounds unencumbered by ligands of low energy, to prepare liquid beryllium compounds of good fluidity and thermal stability, and which have a theoretical  $I_{sp}$  performance goal of at least 330 s with 100%  $\text{H}_2\text{O}_2$ , to tailor the physical properties of these energetic fuels by the substitution of appropriate groups, and to provide compatible and thermally stable vehicles for the formulation of heterogeneous gelled fuels containing suspended solid  $\text{BeH}_2$ . Several approaches to liquid beryllium fuels were pursued: Depolymerization of alkylberyllium hydrides,  $(\text{CH}_3\text{BeH})_x$ , by  $\text{B}_2\text{H}_6$  and  $(\text{CH}_3\text{BeBH}_4)_2$  to form liquids, generation of  $\text{BeH}_2$  *in situ* by hydriding of organoberyllium derivative, dissolution of reactive boron alkyl-terminated  $\text{BeH}_2$  in preformed beryllium liquids and dissolution of  $\text{BeH}_2$  in  $\text{Al}(\text{CH}_3)_3$ . It was demonstrated that liquids containing the components of  $(\text{BeH}_2)_n$  and other beryllium polymers can be prepared when segments of such polymers are suitably terminated with borane (BTBH) or alane (ATBH) groups. An example for the first group of BTBH is  $\text{H}_2\text{BH}_2\text{BeH}_2\text{BeH}_2\text{BH}_2$ , which is still a solid with an enthalpy of formation of  $-131 \text{ kJ/mol}$  ( $-31.4 \text{ kcal/mol}$ ), but its melting point can be lowered by including some methyl groups, such as in  $(\text{CH}_3\text{BeBH}_4)[\text{Be}(\text{CH}_3)_2]_n(\text{BH}_4\text{BeCH}_3)$ . The overall concepts of termination liquefaction and tailoring to achieve good physical properties were exemplified by a sequence including some general physical properties of each compound. In addition to the borane-terminated liquids, alane-terminated liquids have been investigated and found to be suitable media for the formulation of heterogeneous propellants, e.g.,  $(\text{BeH}_2)_n$  gels. The overall objective of these programs is a family of homogeneous and heterogeneous propellants in the 330–360 s  $I_{sp}$  range. Some homogeneous liquid BTBH fuels are reaching the edge of the range and heterogeneous fuels composed of  $(\text{BeH}_2)_n$  gels in ATBH liquids are well within it.

## Binary Metal Hydrides

### 8 Alkali Metal Hydrides

#### 8.1 Lithium Hydride

Pure lithium hydride,  $\text{LiH}$ , CAS RN [7580-67-8], is a white powder and forms colorless, cubic crystals. Commercial grades of lithium hydride are often gray as a result of containing some unreacted elemental lithium.

### 8.1.1 Preparation of Lithium Hydride

Lithium hydride is normally prepared by the action of hydrogen on molten lithium metal at about 973 K (700 °C). This is an exothermic reaction that needs to be controlled by adjusting the hydrogen feed rate. The heavier lithium hydride sinks to the bottom of the reaction vessel as a fluid melt which crystallizes on cooling below the melting point of 961 K (688 °C). Commercial grades of lithium hydride are colored due to the photosensitivity of clear white crystals, and due to impurities caused by incomplete hydrogen absorption. The blueish tint is similar to that of F-centers in irradiated potassium bromide.

Protective coatings have been evaluated for lithium hydride to protect it from the effects of moisture and carbon dioxide in air. Fourteen organic coating materials for protecting lithium hydride from normal atmospheric water vapor were evaluated and weight changes of unprotected and protected specimens were measured as a function of time of exposure [210].

### 8.1.2 Physical Properties of Lithium Hydride

Physical properties of lithium hydride are listed in Table 9. Other summaries of the properties of lithium hydride are published in [211–214].

**Table 9:** Physical properties of lithium hydride.

|                               | SI units                | Other units          |
|-------------------------------|-------------------------|----------------------|
| Molecular mass                | 7.949 g/mol             | 125.8 mol/kg         |
| Melting point                 | 953 K                   | 680 °C               |
| Boiling point                 | Decomposition           | —                    |
| Density at 293 K (20 °C)      | 0.82 g/cm <sup>3</sup>  | —                    |
| Density at 298 K (25 °C)      | 0.775 g/cm <sup>3</sup> | —                    |
| Enthalpy of formation, solid  | –116 kJ/mol             | –27.7 kcal/mol       |
|                               | –90.63 kJ/mol           | –21.66 kcal/mol      |
| Enthalpy of formation, liquid | –77.71 kJ/mol           | –18.57 kcal/mol      |
| Heat of fusion at 961 K       | 25.65 ± 0.50 kJ/mol     | 6.37 ± 0.12 kcal/mol |

#### 8.1.2.1 Density of Lithium Hydride

The density of lithium hydride at 298 K (25 °C) is 0.775 g/cm<sup>3</sup> and the lattice constant of the cubical crystal structure is 4.083 Å. The coefficient of thermal expansion at temperatures from 298 to 798 K (25–525 °C) as measured by XRD may be expressed by the equation:

$$a_t = a_0(\text{at } 25^\circ\text{C}) \left[ 1 + 4.2 \times 10^{-5}(t - 25) + 1.9 \times 10^{-8}(t - 25)^2 \right]$$

where  $a_0$  is the coefficient of thermal expansion at 298 K (25°C) and  $t$  is the temperature in °C. This gives a linear coefficient of expansion of  $4.2 \times 10^{-5} \text{ }^\circ\text{C}^{-1}$  at 298 K (25°C), or a cubical coefficient of expansion of  $1.26 \times 10^{-4} \text{ }^\circ\text{C}^{-1}$ . The density of pressed lithium hydride grains as a function of compacting pressure can be derived from an empirical formula [215, 216].

### 8.1.2.2 Thermal Conductivity of Lithium Hydride

The development of a regression law for lithium hydride grains in hybrid rockets for sizing hybrid engines for different thrust levels depends on accurate data for the thermal conductivity of the fuel grain. The thermal conductivity of pressed lithium hydride grains with a density of  $0.69 \text{ g/cm}^3$  at 673 K (400°C) is  $0.040705 \text{ W cm}^{-1} \text{ K}^{-1} = 3.5 \text{ kcal m}^{-1} \text{ h}^{-1} \text{ }^\circ\text{C}^{-1}$  [217, 218].

The effective thermal conductivity of cast lithium hydride was evaluated as a function of temperature as influenced by non-homogeneous (cracked) distribution, various gases in cracks and voids [219]. The overall effective thermal conductivity of lithium hydride between the outer surface of its container and the surface of an enclosed cooling tube can be established at  $0.1055$  and  $0.05189 \text{ W cm}^{-1} \text{ K}^{-1}$  at 394 and 755 K (6.1 and 3.0  $\text{BTU h}^{-1} \text{ ft}^{-1} \text{ }^\circ\text{F}^{-1}$  at 250 and 900°F), respectively, with a helium internal atmosphere. The thermal conductivity of LiH compacts with 0.7% void increased from 2 to  $100 \text{ W m}^{-1} \text{ K}^{-1}$  between 10 and 70 K, maximized at 50–71 K, and then decreased to  $20 \text{ W m}^{-1} \text{ K}^{-1}$  at room temperature [220].

The thermal conductivity of lithium hydride was measured because it was intended to be used as a nuclear radiation (neutron) shield around nuclear reactors [221]. A large disc of molten lithium hydride, 2.18 m (86 in.) in diameter and weighing 770 kg (1700 lb.) was cast to be used as a radiation shield for a SNAP in-space nuclear reactor. Thermal conductivity data of lithium hydride are listed in Table 10.

Thermal conductivity of solid lithium hydride over the temperature interval 333–783 K (60–510°C) was measured by a stationary radial heat-flux method [222]. The test

**Table 10:** Thermal conductivity of solid lithium hydride.

| Temperature |     | Thermal conductivity             |                                                                 |
|-------------|-----|----------------------------------|-----------------------------------------------------------------|
| K           | °C  | $\text{W m}^{-1} \text{ K}^{-1}$ | $\text{kcal m}^{-1} \text{ h}^{-1} \text{ }^\circ\text{C}^{-1}$ |
| 323         | 50  | 7.79                             | 6.7                                                             |
| 373         | 100 | 6.98                             | 6.01                                                            |
| 423         | 150 | 6.32                             | 5.44                                                            |
| 473         | 200 | 5.74                             | 4.94                                                            |
| 523         | 250 | 5.35                             | 4.6                                                             |
| 573         | 300 | 4.77                             | 4.1                                                             |
| 623         | 350 | 4.39                             | 3.78                                                            |
| 673         | 400 | 4.25                             | 3.66                                                            |

sample was a cylinder constructed from 1.2 to 2.5 cm thick, hollow disks with 1 cm inner diameter and 7 cm outer diameter in a helium atmosphere. The heat flux from the internal heater was measured by means of potential leads and the temperature differential in the range of 15–25 °C was measured with thermocouples placed along the inner and outer surfaces of the disk to be studied. The thermal conductivity of lithium hydride measured by Fieldhouse is given in Table 11. These data are very similar to those in Table 10.

**Table 11:** Thermal conductivity of solid lithium hydride.

| Temperature |     | Thermal conductivity              |                                                       |
|-------------|-----|-----------------------------------|-------------------------------------------------------|

Data source: [222]

The thermal conductivity of lithium hydride was measured using crystal samples placed in various media [213, 223]. One set of measurements was carried out in an inert gas by a relative method involving axial heat flux. The rest of the data (Table 12) were obtained by a method in which the heat flux was determined by measuring the rise in the temperature of gas that passed through a tube inside the lithium hydride test sample (the calorimetric method).

The thermal conductivity of molten lithium hydride can be expressed by the linear equation

$$\lambda = 3.72 \times 10^{-3} T - 2.37$$

where  $\lambda$  is the thermal conductivity in W m<sup>-1</sup> K<sup>-1</sup> and  $T$  is the temperature in kelvin. See also [224].

Lithium hydride cannot be melted unless one operates under hydrogen pressure. The viscosity of molten lithium hydride has been measured in the temperature range 951–1132 K (1252–1578 °F) [225]. A closed system utilizing a Brookfield viscometer was designed for measuring the viscosity of LiH at 951–1132 K. The system was operated under hydrogen at 138 kPa (20 psig) with provisions for external control of the furnace and viscometer. The viscosity varied little and appeared to be described by a straight

**Table 12:** Thermal conductivity of solid lithium hydride obtained by the calorimetric method.

Data source: [213]

line between 0.37 cPs at 951 K and 0.24 cPs at 1128 K. The LiH evidently melted at approximately 951 K, which is 5.5° lower than the reported value.

### 8.1.2.3 Crystal Structure of Lithium Hydride

The crystal structures of the alkali metal hydrides are the same as that of rock salt (NaCl) or zinc sulfide (ZnS). The lattice constant of the cubical crystal structure is 4.083 Å. Single crystals of optical quality LiH can be prepared by slow crystallization of the melt under hydrogen gas at moderate pressure [226]. Measured and reported values of the physical, thermal, chemical, and optical properties of LiH and LiD were compared to those of LiF and NaCl. These properties bear out the predominantly ionic nature of the crystalline LiH structure. The optical properties of LiH differed from those expected by a comparison with the properties of the alkali metal halides or the other alkali metal hydrides. This difference is assumed to be related to distortion and polarization effects on the hydride ion in the LiH crystal lattice. The Li—H bonds may be somewhat covalent which may contribute to the binding energy of crystalline LiH, and this also may be responsible for its somewhat anomalous behavior.

The optical properties of blue color centers involving trapped electrons or ions in LiH showed that properties of the crystalline media other than the lattice parameter are important in relation to the energy of the optical absorption bands [227].

### 8.1.2.4 Thermodynamic Properties of Lithium Hydride

The heat capacity of solid lithium hydride at 293 K (20 °C) is  $C_p = 34.21 \text{ J mol}^{-1} \text{K}^{-1}$  or  $4.305 \text{ J g}^{-1} \text{K}^{-1}$  ( $8.177 \text{ cal mol}^{-1} \text{°C}^{-1}$  or  $c_p = 1.029 \text{ cal g}^{-1} \text{°C}^{-1}$ ). The heat capacity of solid

and liquid lithium hydride as a function of temperature can be calculated from the Shomate equation

$$C_p^\circ = A + B\tau + C\tau^2 + D\tau^3 + E/\tau^2$$

where  $C_p$  is the heat capacity in  $\text{J mol}^{-1} \text{K}^{-1}$ , A, B, C, D, and E are constants and  $\tau$  is the absolute temperature in kelvin divided by 1000. The constants A through E for two phase states are listed in Table 13.

**Table 13:** Coefficients for heat capacity of lithium hydride.

| State                | Solid     | Liquid     |
|----------------------|-----------|------------|
| Temperature range, K | 298–961.8 | 961.8–2000 |
| A                    | 15.45842  | 62.34202   |
| B                    | 52.93220  | 0.00       |
| C                    | −0.099970 | 0.00       |
| D                    | 0.029244  | 0.00       |
| E                    | −0.291667 | 0.00       |

Data source: [10]

The specific heat of LiH between 3.7 and 295 K and entropy and enthalpy at 298 K were obtained from calorimetric measurements [228, 229]. The heat capacities of polycrystalline LiH and LiD were measured by differential scanning calorimeter in the temperature range from 125 to 800 K [230]. The smoothed values of heat capacities were used to calculate various thermodynamic functions for LiH and LiD from 0 to 800 K. The isotopic effect on heat capacity of LiH and LiD was predominant at higher temperatures (> 80 K), whereas below 80 K the isotopic effect was negligible. See also [231].

### 8.1.3 Chemical Properties of Lithium Hydride

#### 8.1.3.1 Hydrolysis of Lithium Hydride

Lithium hydride is resistant to oxygen in dry air, but in moist air it will gradually degrade and turn into useless lithium oxide and lithium hydroxide. While hydrolysis of lithium hydride is very undesirable where it is used as a rocket fuel, this reaction is important where lithium hydride/water reactions are used as a source of hydrogen. The reaction of lithium hydride with sea water can be used to expel ballast water from deep ocean probes and create buoyancy to bring the probe back to the surface [232]. Lithium hydride reacts with water very vigorously developing hydrogen gas. This reaction is a potential hydrogen source for fuel cell applications, although it is not easily reversible. The kinetics of hydrolysis of lithium hydride have been investigated mostly for its use as a source of hydrogen, but the information listed here will now help in assessing potential damage to lithium hydride-containing rocket propellants during

storage in ambient air. The effect of carbon dioxide in ambient air also needs to be considered.

Reactions and reaction products that are formed during reactions of LiH with H<sub>2</sub>O and the reaction kinetics involved were categorized as reactions in low and higher concentration regimes as well as reactions between LiH hydrolysis products [233]. Both LiH and H<sub>2</sub>O can contain various impurities, all of which may affect products and kinetics.

Polycrystalline LiH was reacted with decarbonated H<sub>2</sub>O to determine reaction products, rates, mechanisms, and the effects of experimental parameters [234]. X-ray analyses showed that product oxygen species growth rates had an initial steep rise and then increased linearly with H<sub>2</sub>O exposure time. Increasing H<sub>2</sub>O concentrations increased O growth rate while both increasing temperature and pressure decreased O growth rates. A thin-layer, diffusion-controlled reaction rate was suggested to explain the results, and a growth process for LiOH was illustrated. Micrographs of polycrystalline LiH sections showed a two-phase bulk material and a surface hydrolysis layer with cracks.

The corrosion kinetics of commercial LiH powder (~100 μm, Alfa Aesar) by water vapor in a humidified nitrogen stream was found to be constant in time and first order in gas phase water (<1% relative humidity, RH) [235]. Data obtained using a customized microbalance system equipped with a precision water saturator, dew point analyzer and magnetic sectoring mass spectrometer were used to derive a rough empirical rate expression for the corrosion of the powder by water at low (0.1–0.9%) RH values. These data were consistent with two models: **(1)** a three-layer model and **(2)** rate control by diffusion through a barrier layer.

Hydrolysis of LiH at room temperature and under low RH conditions (RH < 2%) was studied by manometry working with heavy water either in closed (variable water vapor pressure) or open (constant water vapor pressure) systems [236]. Products of the reaction were characterized by XRD and FTIR. It was shown that the hydrolysis reaction occurs in two steps: first water is adsorbed onto the LiH surface and then the hydrolysis reaction starts. In an open system, for relative humidity lower than 0.04% only the formation of Li<sub>2</sub>O was observed while for higher moisture the reaction continued with the production of LiOD. The reaction rate was extremely slow and only a very small amount of LiH was transformed. The kinetics depend on diffusion through the layer of Li<sub>2</sub>O and/or LiOD surrounding the LiH particles. For practical application, it was concluded that if LiH is stored under controlled humidity lower than 0.04% (40 ppm) there is no major risk to form LiOH in significant amounts.

A mechanism describing the hydrolysis of lithium hydride under moist atmosphere involved the formation of lithium oxide (Li<sub>2</sub>O) at low vapor pressure and both Li<sub>2</sub>O and LiOH at higher vapor pressures, with diffusion of water in these layers [237]. A numerical model based on this mechanism was implemented to simulate the hydrolysis of LiH particles in an open system (constant water vapor pressure).

Kinetic parameters in the model such as rate constants of reactions and diffusion coefficients of water in Li<sub>2</sub>O and LiOH were fitted against experimental data. The best agreements were obtained when the diffusion coefficient of water was 10 times higher in LiOH than in Li<sub>2</sub>O. The resulting model accurately predicted the hydrolysis rates experimentally measured for a wide range of water vapor pressures (0.3–17 Pa). The thickness of the Li<sub>2</sub>O layer did not depend much on the water vapor pressure whereas that of LiOH increased drastically at high water vapor pressures.

### 8.1.3.2 Reactions of Lithium Hydride with Other Hydrides

Using simultaneous DTA and TGA and powder XRD, it was determined that the reactions of equimolar amounts of lithium hydride and beryllium hydride follow the pathway

and for reaction mixtures containing  $\geq 66.6$  mol-% LiH or more it follows:

LiBeH<sub>3</sub> melted at 430 K. Li<sub>2</sub>BeH<sub>4</sub> had two thermal transitions at 550 and 660 K; the first may be intramolecular rearrangement and the second may be fusion. The two products were indistinguishable by powder XRD [238, 239].

### 8.1.3.3 Decomposition of Lithium Hydride

All metal hydrides dissociate into the elements at higher temperatures. The dissociation pressures of lithium hydride and other alkali metal hydrides and some alkaline earth metal hydrides are illustrated in Figure 2. Lithium hydride decomposes at  $> 970\text{ K} = > 700^\circ\text{C}$ . Lithium hydride is the second most stable hydride among the group of hydrides shown. Lithium hydride is the only metal hydride known to dissociate reversibly at pressures less than one atmosphere.

The equilibrium dissociation pressures and thermodynamic properties of lithium hydride and lithium deuteride have been determined from 723 to 1023 K (450 to 750 °C) [240]. The dissociation pressure as a function of temperature followed the equation

$$\log_{10} P = B - A/T$$

where  $P$  is the pressure in Pa and  $T$  is the temperature in kelvin. The constants  $A$  and  $B$  differed for solid and molten LiH: solid  $A = 10355 \pm 18$ ,  $B = 14.243 \pm 0.022$ ; liquid  $A = 7675 \pm 30$ ,  $B = 11.456 \pm 0.031$ . The latent heat of fusion was  $25.65 \pm 0.50\text{ kJ/mol}$ . The melting point was 961.8 K. Similar data were obtained for lithium deuteride. See also [241, 242].

The endothermic decomposition of lithium hydride was evaluated as an internal coolant for reentry bodies subjected to intense aerodynamic heating on entering the atmosphere [243, 244]. The dissociation of lithium hydride absorbs 0.75 times as much heat as the vaporization of an equal weight of lithium metal, four times as much as

**Figure 2:** Dissociation pressures of alkali metal hydrides and alkaline earth metal hydrides (republished and modified from [208], with permission of ©2016 John Wiley & Sons; permission conveyed through RightsLink)

sodium metal, and 6.9 times as much as water at a pressure of one atmosphere. The instability temperature  $T_e$  of lithium hydride was found to lie above the observed melting point, in accordance with computer simulation results [245].

#### 8.1.3.4 Photolysis of Lithium Hydride

When clean (colorless) lithium hydride is exposed to intense daylight at room temperature, it can be observed to slowly change in color from white to rose, brown, and finally to gray-blue. Ultraviolet light produces the blue color more rapidly. The coloration lasts indefinitely at room temperature but disappears on heating to 343 K (70 °C). Ionic radiation bombardment at room temperature also produced the blue color (F centers).

#### 8.1.4 Lithium Hydride Fuel Grains

Lithium hydride has been evaluated as a fuel for hybrid rocket engines, in particular with fluorine as the oxidizer [246]. There are at least three different methods to convert LiH powder to solid fuel grains: melt-casting, pressing, and bonding with organic polymers. Lithium hydride can be melted and cast into cylindrical shapes only under

a protective atmosphere of hydrogen, because otherwise it would decompose into the elements [247].

Lithium powder can be pressed into grains with low void content in a die in a hydraulic press without pelletizing aids [215]. The density of grains pressed at very high pressures approached that of single crystals.

### 8.1.5 Applications of Lithium Hydride

Lithium hydride has been proposed as a rocket propellant fuel, as fuel for fusion reactors, as neutron-absorbing radiation shield for nuclear reactors, and as endothermic heat sink for reentry vehicles. Lithium hydride is used in the synthesis of many other metal hydrides, some of which can be used as rocket propellants.

Encapsulated lithium hydride was evaluated as a phase change material for solar-thermal power plants in satellites to maintain operations while in the shade of Earth and as a peak heat load absorbent for pulsed power plants in directed energy beam space weapons, allowing for the design of smaller radiators. The containment of molten lithium hydride at high temperatures and high pressures requires special precautions due to the corrosiveness of the melt and permeation of hydrogen through metals [247].

## 8.2 Sodium Hydride

Sodium hydride, NaH, CAS RN [7646-69-7], has rarely been used as rocket propellant. Its main application is in the synthesis of other hydrides. Its standard enthalpy of formation is  $-56.44$  kJ/mol.

Sodium hydride is usually sold as a dispersion in inert hydrocarbons (kerosene) which may contain up to 25% NaH. The sodium hydride has a higher density than the hydrocarbon and will settle when allowed to stand in a quiet place. Sodium hydride suspensions in kerosene are hypergolic with white fuming nitric acid (WFNA) or red fuming nitric acid (RFNA). Only very small concentrations of NaH are required to hypergolize this very economical combination.

## 9 Alkaline Earth Metal Hydrides

The crystal structures of the alkaline-earth metal hydrides are of the  $\text{PbCl}_2$  type, and only  $\text{MgH}_2$  has the rutile ( $\text{TiO}_2$ ) crystal structure.

## 9.1 Beryllium Hydride

Beryllium hydride, beryllium dihydride,  $\text{BeH}_2$ , CAS RN [7787-52-2], has received a significant amount of attention as a potential rocket propellant. Much of the early work in the US in the 1960s and 1970s was classified confidential. Much of it remains under a limited distribution status, although most of it is obsolete and of less strategic value by now. During the time when much of the beryllium hydride work was classified, beryllium hydride was often referred to under its code name, Light Metal Hydride 2, LMH-2. The number of publications on beryllium hydride climaxed in the 1960s and then dropped off sharply as the interest in  $\text{BeH}_2$  waned. Beryllium hydride is a colorless, amorphous solid that is insoluble in solvents that do not decompose it. See also [248, 249].

### 9.1.1 Preparation of Beryllium Hydride

Different manufacturing methods were sought for light metal hydrides that would provide a solvate-free, high-density product. Much of the early work on beryllium hydride in the mid-1960s was performed by Ethyl Corp. [250]. This resulted in a method for preparing beryllium hydride in high purity (better than 90 mass-%) and in a method for converting the amorphous product to a crystalline high-density form.

#### 9.1.1.1 Preparation of Beryllium Hydride from the Elements

While lithium hydride with an enthalpy of formation of  $-90 \text{ kJ/mol}$  can be directly formed from the elements under pressure, the formation of beryllium hydride with an enthalpy of formation of  $-19 \text{ kJ/mol}$  from the elements is much less likely. The first synthesis of  $\text{BeH}_2$  directly from the elements was reported in 1933 by Pietsch et al. [251], but later questioned on closer examination.

The direct synthesis of beryllium hydride from the elements was attempted, but in vain, in equipment designed to grind beryllium metal powder while subjected to heat and hydrogen pressure [252]. The ability of the equipment to grind metals satisfactorily was demonstrated in test runs, in which magnesium hydride was synthesized from the elements; however, beryllium hydride was not prepared by this method, even when catalytic additives were used. There were no indications even of partial hydriding.

#### 9.1.1.2 Preparation of Beryllium Hydride by Hydride Substitution

Subsequent  $\text{BeH}_2$  syntheses were not directly from the elements, but by reduction of dimethylberyllium with lithium aluminum hydride (lithium alanate)  $\text{LiAlH}_4$  in ether [253, 254]. Another method was the reduction of beryllium chloride  $\text{BeCl}_2$  with lithium hydride, which led to a mixture of  $\text{BeH}_2$ ,  $\text{LiH}$ , and  $\text{LiCl}$  [255], but there are serious doubts about the purity of the first preparations of this compound. Later authors [256] had difficulties repeating the synthesis methods reported by the early investigators. It appears that most of the early preparations contained varying amounts of ether as

an adduct which was difficult to remove. Some  $\text{BeH}_2$  products decomposed at the attempt to remove the ether. The reaction between  $\text{LiAlH}_4$  and  $\text{Be}(\text{CH}_3)_2$  in  $\text{Et}_2\text{O}$  gives a product with ~60 mass-%  $\text{BeH}_2$ .

There are a number of patents covering various methods for preparation of beryllium hydride, but not all of them deliver what they promise. Processes patented include preparing beryllium hydride by the direct reaction of beryllium borohydride and aluminum hydride trimethylamine adduct [257]; reacting anhydrous beryllium chloride with sodium triethyl borohydride [258]; reacting a tetraalkyldiborane of the general formula  $\text{R}_2\text{BH}_2\text{BR}_2$  with a dialkyl beryllium compound of the general formula  $\text{R}_2\text{Be}$  [259]; reacting dialkyl aluminum hydride/trialkyl aluminum with beryllium halides or beryllium alkoxides [260]; reaction of beryllium borohydride etherate with triphenylphosphine, followed by extraction with benzene [261]; reduction of beryllium alkyls with hydrogen under pressure (2000–10000 psi) [262]. Looking at the time elapsed between filing date and publishing date, it appears that many of these patents were under a secrecy order for several years and they were only published in 1973–1975 after some of the restrictions were relaxed.

#### 9.1.1.3 Preparation of Beryllium Hydride by Pyrolysis of Alkylberyllium Compounds

Properties of alkylberyllium compounds are described in *Encyclopedia of Liquid Fuels*, chapter “Organometallic Compounds.” Alkylberyllium compounds are of interest as intermediates in the production of beryllium hydride. Beryllium hydride obtained by pyrolysis of di-*tert*-butylberyllium was more stable [263, 264]. Di-*tert*-butylberyllium decomposed rapidly above 373 K to give mainly beryllium hydride and isobutene. This process has been used for a long time to make amorphous beryllium hydride, which has a relatively low density. Diisopropylberyllium and diethylberyllium have dimer structures and the boiling points are relatively high (553 and 467 K = 280 and 194 °C) for a single metal alkyl molecule. Diisopropylberyllium is thermally more stable than di-*tert*-butylberyllium.

Beryllium hydride can be prepared by the pyrolysis of both pure di-*tert*-butylberyllium and its etherate [265]. Pure di-*tert*-butylberyllium is a clear, colorless, mobile liquid with a density of 0.65 g/cm<sup>3</sup> and a freezing point of 257 K (–16 °C). When freshly prepared, it had a vapor pressure of about 4.7 kPa at 298 K (35 mm Hg at 25 °C). On standing it undergoes slow decomposition at room temperature with the evolution of isobutene. Beryllium hydride prepared by pyrolysis of di-*tert*-butylberyllium had a density of about 0.57 g/cm<sup>3</sup>, evolved hydrogen slowly at 463–473 K (190–200 °C) and rapidly at 493 K (220 °C), was relatively inert to laboratory air, and reacted slowly with water but rapidly with acid. It decomposed only above 523 K (250 °C).

The “Beane” material that was supplied during the early 1960s for propellant evaluation was essentially an amorphous form of undetermined structure with a maximum density of about 0.67 g/cm<sup>3</sup>. In addition to the amorphous form, at least three crystalline polymorphs of beryllium hydride had been identified. The crystal structures of two polymorphs had been determined, one of which had a theoretical

density of  $0.82 \text{ g/cm}^3$ . Crystal structure and theoretical density of the third polymorph were uncertain.

Crystalline as opposed to amorphous beryllium hydride was occasionally encountered in samples prepared by metathetical reduction reactions rather than pyrolysis of beryllium alkyls; however, the degree of crystallinity obtained was quite variable with little or no apparent correlation with processing variables.

Beryllium hydride can be produced in purities of 90–98 mass-% by the controlled pyrolysis of di-*tert*-butylberyllium etherate in hot oil [266]. It was obtained as an amorphous solid, remarkably stable at elevated temperatures and resistant to attack by water and common organic solvents. The source of residual impurities was shown by deuterium labeling to be derived largely from incomplete pyrolysis and ether cleavage. A series of alternate alkylberyllium homologs was subjected to the pyrolysis reaction. Of these di-*tert*-butylberyllium etherate gave the highest purity  $\text{BeH}_2$ . The preparation of crystalline beryllium hydride (average density  $0.78\text{--}0.80 \text{ g/cm}^3$ ) requires the incorporation of lithium hydride and crystallization at elevated temperature and pressure. In practice, instead of adding lithium hydride later, *n*-butyllithium is added to the beryllium alkyl and the resultant solution pyrolyzed to a mixture of amorphous beryllium hydride containing 1.5–2 mass-% lithium hydride.

Studies of the  $\text{Be}(\text{BH}_4)_2/\text{AlR}_3$  reaction system led to the discovery of new forms of beryllium hydride, the borane-terminated beryllium hydrides,  $(\text{BeH}_2)_x(\text{BH}_3)_2$  [267]. These materials had good physical and chemical stability and were essentially equivalent to pure  $\text{BeH}_2$  in theoretical rocket propellant performance. They were, like  $\text{BeH}_2$ , amorphous and of low density, and studies aimed at inducing  $(\text{BeH}_2)_x(\text{BH}_3)_2$  crystallization met with very limited success. Beane (Ethyl Corporation  $\text{BeH}_2$ ) was shown to dissolve smoothly in  $\text{Al}(\text{CH}_3)_3$ , forming a liquid complex; however,  $\text{Al}(\text{CH}_3)_3$  was known to form strong bonds with  $\text{BeH}_2$ , and no attempt was made to recover  $\text{BeH}_2$  from the dissolved complex. During pressure studies of Beane crystallization at pressures up to 150 kilobars (2.2 million psi) it was found that the most important factors in crystallization were the time for which samples were held at given pressure-temperature (*P-T*) conditions, and the rate at which they were quenched back to ambient conditions.

There are a number of patents covering various methods for preparation of beryllium hydride, but not all of them deliver what they promise. Patented processes include pyrolysis of di-*t*-alkyl beryllium etherate at 373–473 K (100–200 °C) [268]; pyrolysis of di-*t*-butyl beryllium etherate with agitation [269]; low-pressure pyrolysis of dialkylberyllium compounds in absence of a solvent [270].

#### 9.1.1.4 Preparation of Beryllium Hydride by Disproportionation

Direct synthesis of dense  $\text{BeH}_2$  was attempted by thermal and chemical dissociation of complexes of  $\text{BeH}_2$  with alkyl derivatives of boron or aluminum [271]. Although  $\text{BeH}_2$  was produced in purities of 93 mass-%, only the low density, amorphous form was obtained. Neutral tertiary amine complexes of  $\text{BeH}_2$  were prepared by heating

pyrolytic BeH<sub>2</sub> with amines. Alkyl, cyclic and aromatic monoamines and diamines of suitable base strength and steric requirements formed Lewis adduct complexes in high yield. The monoamine adducts were white, crystalline solids, soluble in aromatic hydrocarbons and amines. They exist as dimeric species in solution. The diamine complexes were polymeric and were insoluble in aromatic solvents and amines. The weak BeH<sub>2</sub>•amine complexes can be thermally dissociated to high purity BeH<sub>2</sub>, though not crystalline but only amorphous BeH<sub>2</sub>. They represent attractive intermediates in the direct crystallization of BeH<sub>2</sub>. The trimethylamine adduct of BeH<sub>2</sub> was prepared by dissociation of Be(Et<sub>3</sub>AlH)<sub>2</sub> with trimethylamine. The preparation of the intermediate Be(Et<sub>3</sub>AlH)<sub>2</sub> was accomplished in high yield.

Beryllium chloride hydride ClBeH and its etherate which were tested as precursors for the synthesis of BeH<sub>2</sub> can be made in 95% yield from beryllium chloride-etherate and sodium hydride. Disproportionation of the ClBeH intermediate was demonstrated to give beryllium hydride in purities up to 85 mass-% BeH<sub>2</sub> [272]. The disproportionation was retarded in ether as the solvent. A solvent was sought to extract BeCl<sub>2</sub> from the reaction mixture. Although BeCl<sub>2</sub> etherate was extracted by benzene, some Be—Cl bonds retained in the solid. This indicated that some residual Be—Cl bonds were either physically occluded in the solid or chemically bound in the structure. The product was amorphous with residual Be—Cl bonds, retained ether, and Be—O bonds as the major contaminants. The atomic ratio of active hydride to residual chloride in some samples of the final product reached up to 137:1, corresponding to an impurity content of 5 mass-% BeCl<sub>2</sub>. Disproportionation of beryllium chloride hydride under vacuum gave beryllium hydride with purities of up to 88 mass-% and, conversions of up to 87% based on initial ClBeH amount [273]. Lithium aluminum hydride treatment of the final product reduced chloride and ether contaminants to tolerable levels.

#### 9.1.1.5 Crystallization of Beryllium Hydride

Amorphous beryllium hydride has a low density and has widely varying properties. There are only few solvents that would dissolve beryllium hydride and allow it to be recrystallized in a higher density modification. Most solvents will tenaciously adhere as solvates to the recrystallized product.

The crystallization of BeH<sub>2</sub> via compaction-fusion of amorphous pyrolytic material (Beane product) with various metal fluorides as co-additives with lithium hydride, drastically reduced the pressure required to crystallize Beane product in short times [274]. At 2–3 mass-% concentration of the metal fluoride, the pressure requirement was reduced by about 50%. Crystalline BeH<sub>2</sub> used as seed crystals in large concentrations was effective for crystallizing Li-doped BeH<sub>2</sub> at room temperature under high pressure; however, the effectiveness became progressively less with repeated cycling. Be metal, formed *in situ* also was an active crystallization catalyst at lower pressures. Gross crystallization was obtained without use of an extended temperature quench. Attempts to crystallize beryllium hydride via dissociation of tertiary amine complexes

were unsuccessful. The triethylamine and *N*-methylmorpholine complexes of  $\text{BeH}_2$  were successfully prepared for the first time.

Attempts to prepare dense, crystalline beryllium hydride,  $\text{BeH}_2$ , at near atmospheric pressure were largely unsuccessful. Vapor pyrolysis of ether-free di-*tert*-butylberyllium produced  $\text{BeH}_2$  with purities as high as 98 mass-% and without any residual alkyl groups; however, all products were amorphous and of low density. The density of the clear glassy deposit obtained by vapor deposition and growth on the walls of the pyrolysis vessel was  $0.70 \text{ g/cm}^3$ . Attempts to deposit crystalline  $\text{BeH}_2$  by growth from the vapor on various crystalline substrates produced only amorphous material. Solution pyrolysis of dioctylberyllium and dihexylberyllium produced impure, amorphous  $\text{BeH}_2$ . The best product was obtained using dihexylberyllium; however, product purity was only 60–85 mol-%. Thermal dissociation of the  $\text{BeH}_2$  triethylamine complex from a toluene solution in the presence of a seed bed of crystalline  $\text{BeH}_2$  indicated that a small amount of crystalline deposit was formed. The quantity of deposit obtained was too small to obtain unequivocal proof for the feasibility of this method, even though the disassociation was continued for as long as 104 h. Long-term digestion of lithium-doped amorphous  $\text{BeH}_2$  in the presence of such Lewis bases as amines and ethers containing crystalline  $\text{BeH}_2$  as seed also gave inconclusive evidence that partial crystallization was obtained. Extended grinding of mixtures of amorphous and crystalline  $\text{BeH}_2$  in the presence of an inert solvent caused reversion of crystalline material to the amorphous form.

There have been numerous efforts to improve the beryllium hydride products by recrystallizing the amorphous product under pressure or using synthesis routes other than the pyrolysis of di-*tert*-butylberyllium [275–278]. In trying to densify  $\text{BeH}_2$  by crystallization in a suitable solvent, commercially available raw beryllium hydride (an Ethyl Corporation  $\text{BeH}_2$  product called “Beane”) was shown to dissolve smoothly in  $\text{Al}(\text{CH}_3)_3$ , forming a liquid complex; however,  $\text{Al}(\text{CH}_3)_3$  forms strong bonds with  $\text{BeH}_2$ , and no attempt was made to recover pure  $\text{BeH}_2$  from the complex [267]. Pressure studies of Beane crystallization up to 15 GPa (150 kilobars = 2.2 million psi) were carried out, and unadulterated Beane was crystallized for the first time. The most important factors in crystallization proved to be the duration of time for which samples were held at given *P-T* conditions, and the rate at which they were quenched back to ambient conditions. Lithium-doped  $\text{BeH}_2$  was crystallized using a hydrothermal pressure apparatus and this process was planned to be scaled up.

The amorphous  $\text{BeH}_2$  product can be converted to crystalline  $\text{BeH}_2$  by compaction-fusion at an ultrahigh pressure of 1.38 GPa (200000 psi) and 473 K (200 °C). These methods are uneconomical and time-consuming and thus impractical for large-scale production of crystalline  $\text{BeH}_2$ . A sustained effort was directed at the densification of LMH-2 by crystallization under high pressure [279, 280].

The study of  $\text{BeH}_2$  crystallization process parameters has provided a partial phase diagram for the *P-T* regime of 393–523 K (120–250 °C) and 275–965 MPa (40–140 kpsi)

[281]. It showed that both the product density and distribution of crystalline polymorphs are simple functions of the applied pressure and temperature. Hydrostatic compaction time does not appear to be a critical variable. A pressure of at least 275 MPa (40 kpsi) (at about 473 K = 200 °C) and temperature of at least 403 K (130 °C) (with pressures above 620 MPa = 90 kpsi) appear necessary for crystallization. Other reports stated that temperatures of at least 393–408 K (120–135 °C) and pressures greater than 275 MPa (40 kpsi) are required for crystallization. The more thermally stable phase evidently has a higher density (0.77–0.78 g/cm<sup>3</sup>) than the other phase (0.73–0.74 g/cm<sup>3</sup>). A high-density phase is formed preferentially at higher pressures, requiring about 758–827 MPa (110–120 kpsi) for production in its pure form. Small changes in the concentration of the Li dopant or Be metal content did not noticeably affect crystallization or polymorph distribution. Undoped BeH<sub>2</sub> was not crystallized under conditions of 965 MPa (140 kpsi) at 478 K (205 °C) even after 4 h; however, the density was increased to 0.70 g/cm<sup>3</sup>. Encapsulation of BeH<sub>2</sub> appears necessary for successful crystallization by hydrostatic compaction. Various types of metal thimbles and closures were tested as capsules for pre-compaction and crystallization steps.

An effective, practical technique was found for pre-compacting and encapsulating Li-doped BeH<sub>2</sub> prior to crystallization by hydrostatic compaction at elevated temperature [282]. The technique employed seamless aluminum capsules fitted with solid metal plug closures and sealed with Viton O-rings. The powdered feed was pre-compacted within the capsules by use of a piston-mold unit in a platen press. The finely divided BeH<sub>2</sub> feed is easily pre-compacted within the capsule by means of a piston-mold unit operated at the moderate pressure of 48 MPa (7000 psi). The technique was successfully tested in a series of 30 crystallization experiments. No significant change in optimum crystallization conditions or polymorph distribution was observed with this new technique. The feasibility of a ‘slurry’ process for crystallization of BeH<sub>2</sub> by hydrostatic compaction was also demonstrated. Hydrocarbon-wet Li-doped BeH<sub>2</sub> was completely crystallized at temperatures ranging from 478 to 503 K (205–230 °C) and pressures of 482–965 MPa (70–140 kpsi). Two process alternatives, namely dry encapsulation and slurry processes were tested successfully [283]. Temperature quench rate had no effect on extent of crystallization or preferred polymorph. With the slurry process, hydrocarbon-wet BeH<sub>2</sub> was crystallized at pressures of 482–965 MPa (70–140 kpsi) and 478–503 K (205–230 °C); however, concentrations of high-density phase in the product were much lower than those obtained by the dry process under similar operating conditions.

### 9.1.2 Physical Properties of Beryllium Hydride

The physical properties of beryllium hydride (Table 14) are not as clear-cut as the properties of many other rocket propellants. First, the reported properties were for impure preparations, which often contained solvated ether molecules. Then, as much of the research was for military purposes, the results were shrouded for a long time by se-

crecy restrictions. The exact composition and properties of the synthesis products depended on the method of preparation. Beryllium hydride has a melting point of 523 K (250 °C) with decomposition. See also [284].

**Table 14:** Physical properties of beryllium hydride.

### 9.1.2.1 Molecular Structure of Beryllium Hydride

Unlike the ionically bonded hydrides of the heavier Group 2 elements, beryllium hydride is covalently bonded (two or more beryllium atoms linked by three-center two-electron hydrogen bonds). The synthesis of LMH-2 has been plagued by the low density of the product. In an effort to determine the theoretical density of LMH-2, attempts have been made to index X-ray powder photographs of the material. These attempts have been frustrated by low symmetry and lack of purity of phase and composition. Microscopic studies of reported polymorphic transitions were investigated and found to be inconclusive [290]. An early powder diffraction pattern of BeH<sub>2</sub> has been shown to be indexed incorrectly. A radial distribution analysis of the glassy phase of LMH-2 was carried out using XRD methods. The results of the analysis confirmed the theoretical tetrahedral four-fold coordination proposed for the cation.

Beryllium hydride is usually formed as an amorphous white solid, but a hexagonal crystalline form with a higher density was reported, prepared by heating amorphous BeH<sub>2</sub> under pressure. Crystalline BeH<sub>2</sub> was prepared by high-pressure compaction-fusion of amorphous BeH<sub>2</sub> catalyzed by 0.9–2.5 mol % lithium [285], added in the form of lithium hydride or lithium aluminum hydride [291, 292]. Pressures of at least 2.75 kbar (at 473 K = 200 °C) as well as temperatures exceeding 403 K = 130 °C (at 6.2 kbar) were required for the transformation. This was accompanied by an increase in density from  $0.62\text{--}0.65$  g/cm<sup>3</sup> for amorphous BeH<sub>2</sub> to  $0.77\text{--}0.78$  g/cm<sup>3</sup>. Two separate crystalline phases were identified. XRD patterns of the phase were indexed for a hexagonal unit cell with dimensions  $a = 4.20$  Å and  $c = 6.76$  Å with a theoretical XRD density of  $0.82$  g/cm<sup>3</sup>. Because the identification of various amorphous or

polymorphic forms of BeH<sub>2</sub> was not always standardized and uniform among the scientific community, early versions of crystalline BeH<sub>2</sub> were sometimes identified by the two strongest lines in the XRD diffraction pattern instead of Greek letters. For instance, the crystalline hexagonal form phase 338–208 reverted to amorphous BeH<sub>2</sub> after heating to 433 K (160 °C) for several hours.

The crystal and molecular structure of BeH<sub>2</sub> has been determined from high-resolution powder diffraction data obtained at a synchrotron radiation source [293]. The unit cell parameters of the body-centered orthorhombic crystals were  $a = 9.082(4)$  Å,  $b = 4.160(2)$  Å,  $c = 7.707(3)$  Å,  $V = 291.2$  Å<sup>3</sup>, corresponding to space groups, *Ibam* or *Iba2*. The crystal structure is based on a network of corner-sharing BeH<sub>4</sub> tetrahedra rather than flat infinite chains containing hydrogen bridges as previously assumed. The Be–H bond distances were 1.38(2) Å around Be(1) and 1.41(2) Å around Be(2). The H–Be–H tetrahedral bond angles ranged from 107 to 113° and the <Be–H–Be bond angle was approximately 128°. The space group is *Ibam*, and there are 12 BeH<sub>2</sub> molecules in the unit cell. The XRD theoretical density was 0.755 g/cm<sup>3</sup>.

The lattice dynamics of crystalline BeH<sub>2</sub> were studied using a Born-von Karman model [294]. The zone-center frequencies, isotopic shifts and the phonon density of states were calculated. The symmetries of the zone-center modes were determined and the types of ion oscillations were identified.

Crystalline beryllium hydride may undergo an irreversible thermally induced solid-state phase change, with the product being amorphous or glassy beryllium hydride [295]. The phase change was observed using simultaneous DTA/TGA and XRD. The phase change took place at 485–550 K, just below the thermal decomposition temperature of 570 K. There was slight decomposition of the beryllium hydride during the phase change of about  $5 \pm 2\%$ . The enthalpy change associated with the phase transition was  $2.3 \pm 0.7$  kJ/mol.

The crystal structure, mechanical properties and electronic structure of ground state BeH<sub>2</sub> were calculated employing the first-principles methods based on density functional theory [296]. The calculated structural parameters at equilibrium volume were consistent with experimental results. The bulk modulus *B*, shear modulus *G*, Young's modulus *E* and Poisson's ratio  $\nu$  were deduced from the elastic constants. The bonding nature in BeH<sub>2</sub> was fully interpreted by combining characteristics in band structure, density of states, and charge distribution. The ionicity in the Be–H bond is mainly featured by charge transfer from Be 2s to H 1s atomic orbitals while its covalency is dominated by the hybridization of H 1s and Be 2p states. An analysis of BeH<sub>2</sub> described the ionic/covalent character quantitatively and it was found that about 1.6 electrons transfer from each Be atom to H atoms.

The theory of electronic and structural properties, ionization potential (IP), electron affinity (EA), polarizability ( $\alpha$ ), chemical potential ( $\mu$ ), hardness ( $\eta$ ), softness (*S*), band gap and spectral characteristics of beryllium hydride oligomers were analyzed by quantum chemical calculations [297]. The discrepancies in the calculated reactive descriptors of molecules were presumably due to variations in electron distribu-

tion and spin pairing near Fermi level. The molecules  $\text{BeH}_2$ ,  $\text{Be}_3\text{H}_5$ ,  $\text{Be}_5\text{H}_{10}$ ,  $\text{Be}_7\text{H}_{14}$ , and  $\text{Be}_9\text{H}_{18}$  were predicted to be more stable than  $\text{Be}_2\text{H}_4$ ,  $\text{Be}_4\text{H}_8$ ,  $\text{Be}_6\text{H}_{12}$ ,  $\text{Be}_8\text{H}_{16}$ , and  $\text{Be}_{10}\text{H}_{20}$ . Ultra-soft pseudopotentials for electron-nuclei interactions with local density approximation and generalized gradient approximation have been used to interpret the nature of bonding in crystalline beryllium hydride. The observed band gap value of crystalline  $\text{BeH}_2$  is comparable with the band gap value of beryllium hydride oligomers.

### 9.1.2.2 Optical Properties of Beryllium Hydride

Laser-ablated beryllium atoms react with  $\text{H}_2$  upon co-condensation in excess frozen hydrogen and neon to form  $\text{BeH}_2$  and  $(\text{BeH}_2)_2$ , which were identified through isotopic substitution as supported by DFT calculations [298]. Unreacted Be atoms isolated in solid neon or solid hydrogen are atoms in excited states and react further with  $\text{H}_2$  to enhance the  $\text{BeH}_2$  and  $(\text{BeH}_2)_2$  concentrations and produce  $(\text{BeH}_2)_n$  polymers.  $\text{BeH}_2$  molecules associate upon diffusion in solid hydrogen to form one-dimensional  $(\text{BeH}_2)_n$  polymers. The series of strong IR-active parallel Be—H—Be bridge-bond stretching modes observed for  $(\text{BeH}_2)_n$  polymers suggested one-dimensional structures, and this conclusion was supported by DFT calculations. The computed polymerization energy per  $\text{BeH}_2$  unit was about 138 kJ/mol (33 kcal/mol).

The vibrational density of states of amorphous beryllium hydride ( $\alpha\text{-BeH}_2$ ) and lithium beryllium hydrides were studied using inelastic neutron scattering, IR, and Raman spectroscopy [299]. The positions of the symmetrical (120–180 meV) and anti-symmetrical (200–260 meV) Be—H stretching modes and those of the H—Be—H bending mode (50–120 meV) were determined and the results were compared with theoretical calculations. The addition of lithium to the beryllium hydride network shifted the vibrational bands to lower energies, indicating a less rigid network.

### 9.1.3 Chemical Properties of Beryllium Hydride

Beryllium hydride is inert against oxygen in dry atmospheric air. It hydrolyzes in water only slowly at room temperature. Dilute mineral acids will destroy and dissolve it. Beryllium hydride is insoluble in all ordinary solvents. Beryllium hydride reacts with and dissolves in complexing solvents, such as tertiary amines,  $\text{AlR}_3$  or  $\text{BeR}_2$ . Raw beryllium hydride contains several percent of alkyl groups. Almost half the residual alkyl groups are ethyl groups. This indicates that ether cleavage is one of the more important sources of impurities in the product. Total oxygen content of typical Beane product, as determined by neutron activation analysis, averages about 1–3 mass-%. It is present as oxide, hydroxide, and alkoxide groups.

#### 9.1.3.1 Reactions of Beryllium Hydride

The crystalline form of  $\text{BeH}_2$  was slightly more reactive with protonic solvents than amorphous  $\text{BeH}_2$ . Passivation treatment was required for use with usual binders and

plasticizers. Part of this increased reactivity was due to the lithium hydride that was added as a crystallization aid.

#### 9.1.3.2 Reactions with Other Metal Hydrides

Lithium hydride and beryllium hydride powder have been mixed and heated. In the hydride reaction, 1 atom of hydrogen was released at 500–600 K and almost 2 atoms were released at 675 K. XRD showed the formation of  $\text{Li}_2\text{BeH}_4$  plus an unknown lithium-beryllium hydride at temperatures as low as 343 K [300]. The yield of these compounds decreased with increasing temperature and was as high as 60–100% at 350–400 K. Identical behavior was seen with crystalline and non-crystalline  $\text{BeH}_2$ . The  $\text{LiH-BeH}_2$  reaction is thought to create enough heat to temporarily melt the products. Released hydrogen gas or organic vapors then push the material into a foam at 440–470 K. The addition reactions with lithium hydride where the hydride ion is the Lewis base, form sequentially  $\text{LiBeH}_3$  and  $\text{Li}_2\text{BeH}_4$ .

#### 9.1.3.3 Hydrolysis of Beryllium Hydride

Beryllium hydride reacts slowly with water but is rapidly hydrolyzed by acids, such as hydrogen chloride to form beryllium chloride.

#### 9.1.3.4 Reactions of Beryllium Hydride with Lewis Bases

Beryllium hydride reacts with trimethylamine,  $\text{N}(\text{CH}_3)_3$  to form a dimeric adduct, with bridging hydrides [301]; however, with dimethylamine,  $\text{HN}(\text{CH}_3)_2$ , it forms a trimeric beryllium diamide,  $[\text{Be}(\text{N}(\text{CH}_3)_2)_2]_3$  and loses its hydride hydrogen. The addition reactions with lithium hydride where the hydride ion is the Lewis base, form sequentially two different compounds,  $\text{LiBeH}_3$  and  $\text{Li}_2\text{BeH}_4$ . Several tertiary amine complexes of beryllium hydride have been synthesized by three different preparative routes. In the first, trimethylamine allowed to react with the liquid adduct diethylberyllium-diethylaluminum hydride produced a crystalline beryllium complex. The other two procedures involved direct reaction between the amine and polymeric beryllium hydride either by (1) heating the mixture in a sealed system, or (2) ball-milling the reactants together. The complexes were characterized by chemical analysis, IR and NMR spectra, and XRD. These data, along with molecular weight determinations, indicated that the fundamental unit in every case is the hydrogen-bridged  $\text{BeH}_2$  dimer. Beryllium hydride reacts with ammonia or hydrazine under evolution of hydrogen but is stable when dispersed in UDMH.

#### 9.1.3.5 Thermal Decomposition of Beryllium Hydride

Both lithium hydride and beryllium hydride had been considered as materials for radiation shields (neutron shields) around nuclear reactors but the thermal stability of beryllium hydride was found to be insufficient for this task. An investigation of the thermal stability of  $\text{BeH}_2$  showed that after an induction period, the compound would decompose irreversibly.

The kinetics of decomposition and deflagration of a solid propellant containing beryllium hydride (LMH-2) was studied by flash pyrolysis combined with kinetic spectroscopy to determine the cause of low combustion efficiency [302]. The mechanism of deflagration and combustion of beryllium hydride above 2000 K showed the existence of BeH and  $\text{BeH}^+$ . In the temperature range 2200–2800 K, the species BeH appeared to be about three times as plentiful as the ion  $\text{BeH}^+$ . The  $\text{BeH}^+$  ion appears to be more stable at high temperatures than BeH, although it accounts for only a small fraction of the gaseous beryllium-containing decomposition product. The large amount of  $\text{BeH}^+$  found in the deflagration products of beryllium hydride may be responsible for the low combustion efficiency. Because of its low reactivity, this charged ion can pass through the combustion chamber and rocket nozzle without undergoing appreciable reaction with the  $\text{NH}_4\text{ClO}_4$  oxidizer or its decomposition products.

The flash-pyrolysis decomposition of  $\text{BeH}_2$  and  $\text{AlH}_3$  has been studied by kinetic spectroscopy at 2477 K. A combined flash heating-flash photolysis apparatus was used to study very fast reactions in the decomposition of metal hydrides. In this apparatus it was possible to study the chemistry of the gas-phase immediately above the flash-pyrolyzed solid. Additionally, the apparatus can be used for the more familiar technique of flash photolysis [303]. The first product seen in the flash pyrolysis of  $\text{BeH}_2$  was BeH. Within a few microseconds of the appearance, the BeH was seen to decrease in intensity. At 25  $\mu\text{s}$  after the photoflash the first bands of  $\text{BeH}^+$  were seen. From 60  $\mu\text{s}$  on, the  $\text{BeH}^+$  was the major beryllium-containing pyrolysis product. The flash-induced combustion of  $\text{BeH}_2$  in oxygen has been studied at 20 mm pressure of oxygen. The absorption spectra of OH, BeH,  $\text{BeH}^+$ , and BeO were observed, and the relative concentration of each was measured for 140  $\mu\text{s}$  following the initial photoflash. This was the basis of a proposed mechanism for the combustion of  $\text{BeH}_2$ .

#### 9.1.4 Applications of Beryllium Hydride in Rocket Propellants

During the 1960s, when much of the work on beryllium hydride was still classified “Confidential” or even “Secret,” this hydride was known under the code name “LMH-2” or the trade name “Beane.” Research grants adding up to several million dollars were issued to further the production and rocket propellant use of beryllium hydride, all driven by the desire to develop rocket propellants with higher specific impulse, but ultimately the concern about toxicity of the exhaust put an end to all that effort.

##### 9.1.4.1 Applications of Beryllium Hydride in Solid Rocket Propellants

Applications of beryllium hydride in solid propellants will be discussed in future volumes on solid propellants.

#### 9.1.4.2 Applications of Beryllium Hydride in Liquid Monopropellants

Generally metal hydrides like LiH or B<sub>2</sub>H<sub>6</sub> are quite sensitive to moisture but apparently one form of BeH<sub>2</sub> is not sensitive to moisture or H<sub>2</sub>O<sub>2</sub>. A metallized monopropellant has been patented consisting of 26 parts powdered BeH<sub>2</sub>, 5 parts 7–10 nm fumed silica as a gelling agent and 59 parts 98% H<sub>2</sub>O<sub>2</sub>, first mixed in a high-shear blender and later diluted with 59 parts of water and blended again to obtain a thixotropic gelled propellant with a specific impulse of 317 s [304]. Nothing was said about the storage stability of this propellant.

#### 9.1.4.3 Applications of Beryllium Hydride in Liquid Bipropellant Fuels

Beryllium hydride can be suspended in gelled liquid fuels and burned with a variety of liquid oxidizers. In some instances, beryllium hydride suspended in a non-hypergolic hydrocarbon or ether fuel may not only increase the specific impulse but may also make the combination hypergolic when previously it was not.

Beryllium hydride has been evaluated as an additive to both non-hypergolic and hypergolic fuels and the storage stability of BeH<sub>2</sub> in liquid carriers has been investigated. Long-term storage stability tests were made with slurries of beryllium hydride and organometallic liquid carriers at 305 K (90 °F) [305, 306]. Systems containing triethylaluminum, diethylaluminum hydride, diethylberyllium, and triethylborane at 23% ullage evolved gas at 0.6–0.006 cm<sup>3</sup> lb<sup>-1</sup> min<sup>-1</sup>. Systems containing trimethylaluminum and dimethylaluminum hydride produced gas at a rate of 8–19 cm<sup>3</sup> lb<sup>-1</sup> min<sup>-1</sup>. The complex Be(Et<sub>3</sub>AlH)<sub>2</sub> is completely stable but when slurried with beryllium hydride it developed gas at 0.00004 cm<sup>3</sup> lb<sup>-1</sup> min<sup>-1</sup>. The Be(Et<sub>2</sub>BH<sub>2</sub>)<sub>2</sub> complex either alone or mixed with beryllium hydride evolved hydrogen at a rate of about 0.00044 cm<sup>3</sup> lb<sup>-1</sup> min<sup>-1</sup>. The source of initial gassing was found to be gases (mostly nitrogen) adsorbed on the surface of the beryllium hydride. A vacuum bake at 403 K (130 °C) followed by treatment with helium largely eliminated initial gassing and improved the material handling properties.

The compatibility of pyrolytic beryllium hydride (Beane product) with various liquid organometallic compounds was evaluated by measuring the rate of pressure rise of slurries of beryllium hydride in these liquids in a closed system at 305 K (90 °F) [307]. Methyl and ethyl derivatives of beryllium, boron, and aluminum, and their complexes with beryllium hydride were tested for compatibility with beryllium hydride. All systems were characterized by an initial rapid pressure rise, followed by a levelling off until a constant rate of pressure increase was established. The initial large pressure rise has been attributed to desorption of gases (nitrogen) adsorbed on the beryllium hydride surface and can be minimized by baking the beryllium hydride *in vacuo* and storing it under helium. Of the liquids tested, the smallest pressure rise was obtained with diethylberyllium; however, the BeH<sub>2</sub>-Et<sub>2</sub>BeH slurry became completely solid during the course of the compatibility testing period. The standard heats of formation of the complexes, Be(Et<sub>3</sub>AlH)<sub>2</sub> and Be(Et<sub>2</sub>BH<sub>2</sub>)<sub>2</sub> were measured to be  $-282 \pm 43$  kJ/mol

( $-67.3 \pm 10.4$  kcal/mol) and  $-310 \pm 167$  kJ/mol ( $-74 \pm 40$  kcal/mol), respectively. The large errors arise from inaccuracies in the values for the heats of formation of diethylaluminum hydride and triethylborane.

#### 9.1.4.4 Beryllium Hydride Slurries in Hypergolic Bipropellant Fuels

The preferred hypergolic fuel where beryllium hydride would be suspended to increase performance is methylhydrazine (MMH). Several programs have evaluated the storability, ignition and combustion behavior of gelled  $\text{BeH}_2$ /MMH fuels [308]. The dispersion of high percentages of  $\text{BeH}_2$  in liquid fuels continues to be attractive because the resulting fluids when combined with all currently known oxidizers potentially provide storable liquid propellants with very high specific impulse. The calculated theoretical  $I_{sp}$  of  $\text{BeH}_2$  in thickened or gelled MMH would be 350 s with hydrogen peroxide for a 45 mass-% dispersion. Early work showed that fluid dispersions containing more than 20 mass-% of Beane in MMH could not be prepared unless the Beane particles were modified.

LMH-2 powders were treated with a variety of organic chemicals and water in order to find a gas or vapor that would adsorb permanently to the powders and produce surfaces that would not decompose in the presence of MMH [309]. The Lewis acids boron trifluoride and thionyl chloride chemisorbed to the LMH-2 powders and showed good potential for producing a permanently adsorbed film capable of stabilizing the LMH-2/MMH system. Preliminary rheological studies indicated that guar gum, carboxymethylcellulose, agar-agar, Carbopol 940, and Gantrez could thicken or gel MMH, but all reacted with MMH, liberating methane and other gases. Preliminary stability tests on LMH-2/MMH slurries revealed high gas evolution rates that were attributable primarily to hydride degradation. Heat treating the LMH-2 decreased the rate of decomposition.

## 9.2 Magnesium Hydride

Magnesium hydride, magnesium dihydride,  $\text{MgH}_2$ , CAS RN [7693-27-8], is a white powder. It could be used as a less toxic, low-cost replacement for beryllium hydride. Magnesium hydride can be prepared by reaction of magnesium halides with lithium borohydride. It forms also as a result of disproportionation of magnesium bromide hydride [310] or by pyrolysis of alkyl magnesium halide compounds [311]. Magnesium hydride can be prepared from the elements by direct hydrogenation of Mg metal at high pressures and temperatures (200 atm, 500 °C) with  $\text{MgI}_2$  catalyst.

### 9.2.1 Physical Properties of Magnesium Hydride

Physical properties of magnesium hydride are summarized in Table 15.

**Table 15:** Physical properties of magnesium hydride.

|                       | SI units                | Other units                  | References |
|-----------------------|-------------------------|------------------------------|------------|
| Molecular mass        | 26.3209 g/mol           | 37.993 mol/kg                | [10]       |
| Density at 293 K      | 1.45 g/cm <sup>3</sup>  | —                            | [312]      |
|                       | 1.419 g/cm <sup>3</sup> | —                            | [313]      |
|                       | 1.45 g/cm <sup>3</sup>  | 0.0524 lb/in. <sup>3</sup>   | [286]      |
|                       | 523 K decomp.           | 250 °C decomp.               | —          |
| Melting point         | 523 K decomp.           | 250 °C decomp.               | —          |
|                       | —71.03 kJ/mol           | −645 cal/g = −16.98 kcal/mol | [286]      |
|                       | −90.8 kJ/mol            | −21.71 kcal/mol              | [313]      |
|                       | −75.4 kJ/mol            | −18.02 kcal/mol              | [208]      |
|                       | −74.9 kJ/mol            | −17.9 kcal/mol               | [287]      |
| Enthalpy of formation | −76.15 kJ/mol           | −18.20 kcal/mol              | [10]       |
|                       | —                       | —                            | —          |
|                       | —                       | —                            | —          |
|                       | —                       | —                            | —          |
|                       | —                       | —                            | —          |

The heat capacity of magnesium hydride as a function of temperature can be calculated from the following polynomial Shomate equation which was obtained from NIST Chemistry WebBook:

$$C_p^\circ = A + B \times \tau + C \times \tau^2 + D \times \tau^3 + E/\tau^2$$

where  $C_p$  is the molar heat capacity in  $\text{J mol}^{-1} \text{K}^{-1}$ ,  $\tau$  is the temperature in kelvin divided by 1000 and A, B, C, D, and E are constants listed in Table 16. One must note that  $\text{MgH}_2$  is unstable at temperatures above 600 K and the column for the higher temperature range 600–2000 K is only of academic interest.

**Table 16:** Thermodynamic property polynomial equation coefficients for magnesium hydride.

| Temperature range, K | 298–2000  |
|----------------------|-----------|
| A                    | 13.30646  |
| B                    | 103.1607  |
| C                    | −60.36801 |
| D                    | 12.17967  |
| E                    | −0.332913 |
| F                    | −85.32850 |
| H                    | −76.14922 |

Data source: [10]

The enthalpy of formation of magnesium hydride as a function of temperature can be calculated from the following polynomial equation:

$$H^\circ - H_{298.15}^\circ = A \times \tau + B \times \tau^2/2 + C \times \tau^3/3 + D \times \tau^4/4 - E/\tau + F - H$$

where  $H^\circ - H_{298.15}^\circ$  is the excess enthalpy in kJ/mol,  $\tau$  is the temperature in kelvin divided by 1000 and A, B, C, D, E, F, and H are constants listed in Table 16.

### 9.2.2 Chemical Properties of Magnesium Hydride

Magnesium hydride readily and irreversibly reacts with water to form hydrogen gas:

The controlled hydrolysis of magnesium hydride is a candidate method for hydrogen storage as a supply of hydrogen for fuel cells. The hydrolysis of  $\text{MgH}_2$  is very slow unless it is carried out in acidic or alkaline solutions [314, 315] or in the presence of ammonium salts [316]. At 560 K (287 °C) magnesium hydride decomposes to produce  $\text{H}_2$  gas at 100 kPa pressure, but the high temperature required is seen as a limitation in the use of  $\text{MgH}_2$  as a reversible hydrogen storage medium.

## 10 Trivalent Metal Hydrides

### 10.1 Boron Hydrides

Logically, boron hydrides (boranes) should be discussed at this location along with other trivalent hydrides between beryllium hydride and the higher metal hydrides; however, the chemistry of boranes is so complex and involves so much information that this topic has been moved to a chapter of its own: “Boranes.” Complex boron hydrides (“boranates”) will be discussed at the end of the section on the binary hydrides.

### 10.2 Aluminum Hydride

Aluminum hydride,  $\text{AlH}_3$ , alane, aluminum trihydride, alumane, CAS RN [7784-21-6], is a white powder that at room temperature usually exists in a polymeric form. It is very sensitive to air and moisture. Aluminum hydride has a good chance to be used as a rocket propellant, because it is not as toxic and as expensive to produce as beryllium hydride. Anhydrous aluminum chloride as the starting material for aluminum hydride production is readily available in large quantities. During the 1960s, when some of the work on aluminum hydride was still classified as “Confidential,” this hydride was known under the code name “LMH-1.”

Although aluminum hydride has been investigated as a rocket propellant repeatedly and for a very long time since the first examinations became public [317, 318], there has been little progress and it has not yet been widely used as a solid propellant ingredient. Quality, solvate contamination and reproducibility were ongoing and lasting problems since day one when this compound was first proposed as a rocket propellant. The viability of further research on aluminum hydride as a rocket propellant ingredient has been critically reviewed. In the final analysis, it was determined that alane in typical solid propellants offered potentially very high  $I_{sp}$ , but this was traded against the resultant low density relative to use of aluminum alone. The most signif-

icant hurdle, however, was the apparent thermal instability of the material since the decomposition is autocatalytic. This led to an impractical shelf life for the developed formulations and ultimately, to the abandonment of alane as an energetic material in the United States in the 1990s. The interest in alane was revived when a higher quality of crystallized alane became available from foreign sources in 2001.

This chapter on aluminum hydride would be a very short chapter were it not for its ability to serve as a storage medium for hydrogen gas that is intended as an energy carrier for automobile and other vehicle propulsion [319]. The volumetric hydrogen storage capacity of  $\text{AlH}_3$  is 0.148 g/mL, which is twice as much as the density of liquid hydrogen (0.070 g/mL). The recent hydrogen storage work has revived the interest in aluminum hydride and it may eventually become available in commercial quantities for that application. Its eventual application as a rocket propellant would then benefit from the  $\text{AlH}_3$  production capacity established in the hydrogen storage industry, which would greatly exceed the amount of aluminum hydride consumed as a rocket propellant, another example of synergy and down-to-earth benefits derived from space technology.

### 10.2.1 Literature Summaries on Aluminum Hydride

Since aluminum hydride has been known for a long time, there are numerous literature summaries that are far more detailed than what we can offer here in this book [320–323].

### 10.2.2 Preparation of Aluminum Hydride

Aluminum hydride was first reported as an impure solid or as an etherate or as an amine adduct. Aluminum hydride can be prepared by reduction of anhydrous aluminum chloride with lithium aluminum hydride in ether [254, 324].

This reaction yields an unstable solution because the solvated aluminum hydride precipitates after a while. The delay of precipitation is dependent on concentration and temperature. This instability of the solution was assumed to be due to polymerization of  $\text{AlH}_3$ , but this could not be confirmed by molecular mass measurements. The solvated ether could not be removed without decomposition of aluminum hydride to its elements.

It is difficult to recrystallize  $\text{AlH}_3$  to create crystals suitable for XRD structure determination without occlusion of solvent molecules [325]. The solubility of aluminum hydride in various solvents was measured for that purpose. Continuous, direct crystallization of aluminum hydride was studied and achieved in a draft tube baffle crystallizer. Four methods of thermally seeding the crystallizer were examined. Solution stability was a problem. Photomicrographs were taken of the nucleation and growth processes occurring during decomposition of aluminum hydride.

Magnesium has been incorporated as a stabilizer into  $\text{AlH}_3$  made by a continuous crystallization technique and improved thermal stability was achieved in products from a larger process unit [326]. The complex hydride  $\text{LiMg}(\text{AlH}_4)_3$  has been used as the Mg doping agent and magnesium concentrations of 1% were achieved. Flame photometry was used to determine the equivalence point of the  $\text{AlCl}_3 + \text{LiAlH}_4$  reaction for aluminum hydride synthesis in the presence of an excess of  $\text{LiAlH}_4$ . The optimum conditions for the nucleation of  $\alpha\text{-AlH}_3$  and growth of good crystals were very different. A continuous crystallizer would require a continuous feed of seed crystals. Macrocrystalline, Mg-doped and diphenylacetylene (DPA)-treated  $\text{AlH}_3$  showed no improvement in thermal stability after it was kept in a pressure bomb under 52 MPa (7500 psia) hydrogen at room temperature for 5 months. Double base propellant containing magnesium-doped, *in situ* DPA-treated  $\text{AlH}_3$  showed a twofold improvement in stability over standard hydride when stored at 298 or 313 K (25 or 40 °C). Magnesium-doped, *in situ* DPA-treated and magnesium-doped aged  $\text{AlH}_3$  were remarkably stable at 333 K (60 °C). Propellants containing aged magnesium-doped  $\text{AlH}_3$  decomposed only 0.74% after 243 days. Magnesium-doped, *in situ* DPA-treated  $\text{AlH}_3$  in a double base propellant suffered 1% decomposition in 173 days, while in a composite propellant it suffered 0.84% decomposition in 91 days.

Non-solvated aluminum hydride can be prepared from an alkali metal hydride with aluminum chloride in ether solution in the presence of lithium aluminum hydride [327]. Macrocrystalline unsolvated aluminum hydride can be obtained via a  $\text{NaAlH}_4 + \text{AlCl}_3$  route by a process which involves synthesis and further treatment in a 1:1 ether-toluene medium [328]. This process is considerably more economical and yields a superior product compared with the conventional  $\text{LiAlH}_4 + \text{AlCl}_3$  route. One of the solvents used to precipitate alane from its ether solutions is toluene [329, 330].

Six crystalline phases of non-solvated aluminum hydride were prepared by heating aluminum hydride etherate in the presence of a small excess of lithium aluminum hydride  $\text{LiAlH}_4$  [331]. The most stable  $\alpha\text{-AlH}_3$  was prepared from both the solid metastable phases and by crystallizing directly from a refluxing diethyl ether/benzene solution at 349 K (76 °C). Thermal stability and ease of preparation of  $\text{AlH}_3$  were highly dependent on its purity. A product of high purity  $\alpha\text{-AlH}_3$  in the shape of hexagonal macrocrystals was obtained by refluxing  $\text{AlH}_3(n\text{-Pr})_2\text{O}$  with a diethyl ether-benzene solution [332].

Interactions in the  $\text{LiAlH}_4/\text{AlH}_3/\text{Et}_2\text{O}$ ,  $\text{LiBH}_4/\text{AlH}_3/\text{Et}_2\text{O}$ ,  $\text{Mg}(\text{AlH}_4)_2/\text{AlH}_3/\text{Et}_2\text{O}$ , and  $\text{Li}_2\text{Mg}(\text{AlH}_4)_4/\text{AlH}_3/\text{Et}_2\text{O}$  systems leading to formation of unsolvated  $\text{AlH}_3$  were studied by chemical analysis and IR-spectroscopy [333, 334]. Complexes of the compositions  $\text{LiAlH}_4 \bullet 4\text{AlH}_3 \bullet 4\text{Et}_2\text{O}$  (**1**) and  $2\text{LiAlH}_4 \bullet \text{AlH}_3 \bullet 4\text{Et}_2\text{O}$  (**2**) were extracted from the first system and complexes  $\text{LiBH}_4 \bullet \text{AlH}_3 \bullet 2\text{Et}_2\text{O}$  (**3**) and  $\text{LiBH}_4 \bullet 2\text{AlH}_3 \bullet 3\text{Et}_2\text{O}$  (**4**) from the second one. Systems on the basis of magnesium alumohydride are the systems of the eutonic type. Controlled decomposition of crystal compounds (**1**) and (**2**) and their solutions in ether-toluene media leads to formation of  $\text{LiAlH}_4$  with  $\alpha$ -,  $\alpha'$ -, and

$\gamma$ -AlH<sub>3</sub> mixtures, and the decomposition of crystal compound **(4)** leads to formation of LiBH<sub>4</sub>•AlH<sub>3</sub>•0.33Et<sub>2</sub>O. Pure  $\alpha$ -modification of unsolvated aluminum hydride is thus formed by the combined presence of complexes **(1)** and **(4)**. Under those conditions, apparently only the  $\alpha$ -alane form is observed. Other syntheses of aluminum hydride start with sodium hydride and aluminum trichloride in diethyl ether [335] or calcium hydride and aluminum chloride in diethyl ether [336].

$\alpha$ -AlH<sub>3</sub> was also named LMH-1451 [337]. At one time, high-purity material was produced at a production rate of 1000 lb/day via a continuous process. While pure, the quality of the crystals was lacking. The crystals suffered from poor morphology (porous, lower overall density  $\rho = 1.474 \text{ g/cm}^3$ ), and poor long-term stability. In 2001 a sample of Russian (FSU) AlH<sub>3</sub> was obtained in the US and compared to a domestic product from ATK. The Russian AlH<sub>3</sub> was of superior quality with very uniform crystal shapes and narrow particle size distribution range centered at 22  $\mu\text{m}$ . In the hydrogen generation stability test at 316 and 330 K (43 and 57 °C), the ATK material behaved similarly to FSU material at elevated temperatures. In developing a scalable AlH<sub>3</sub> production process, it was noted that several alane polymorphs would survive work-up and can contaminate the  $\alpha$ -phase product. Multiple polymorph combinations were occasionally observed. Finding a scaleable, reproducible process has proven very challenging.

During a study of the crystallization of non-solvated aluminum hydride from a diethyl ether/benzene mixed solvent it was found that the desolvation of AlH<sub>3</sub>•(Et<sub>2</sub>O)<sub>x</sub> etherate in solution and the crystallization of  $\alpha$ -AlH<sub>3</sub> during polythermal heating of the solution occur only in the presence of ~10 mass-% LiAlH<sub>4</sub> [338]. The process is multi-stage, and the crystallization begins with the formation of the AlH<sub>3</sub>•0.25Et<sub>2</sub>O solvate, which recrystallizes in the solid phase into  $\gamma$ -AlH<sub>3</sub> and then  $\alpha$ -AlH<sub>3</sub>. Four crystalline modifications of aluminum hydride were characterized by XRD and electron microscopy. See also [339].

Aluminum hydride has been proposed as a hydrogen storage medium and synthesized electrochemically, providing a synthetic route which closes a reversible cycle for regeneration of the material [340]. The electrolysis of NaAlH<sub>4</sub> in THF gives sodium metal and AlH<sub>3</sub>. For hydrogen storage, AlH<sub>3</sub> would be an excellent candidate if it could be cheaply produced. It has a density of 1.48 g/cm<sup>3</sup>, a volumetric hydrogen storage capacity of 0.148 g/cm<sup>3</sup>, i.e. greater than that of liquid hydrogen (0.070 g/cm<sup>3</sup>) and a hydrogen mass capacity exceeding 10 mass-%.

Aluminum hydride is typically synthesized in ether solution. The ether clings tenaciously to the solid product. The residual ether content of AlH<sub>3</sub> can be determined by gas chromatography [341].

Crystalline aluminum hydride can be prepared using an organometallic synthesis method with changed heat treatment conditions and crystallization conditions in toluene. Crystalline alane samples were characterized using Raman spectroscopy, XRD, and TGA-DTA [342]. It seems to be difficult to obtain pure  $\alpha$ -AlH<sub>3</sub> by heat

treatment of  $\alpha$ -AlH<sub>3</sub> etherate. Treating samples mostly containing the crystalline  $\alpha$  form of alane with dilute acid induced a better thermal stability. Aluminum hydride has a volumetric hydrogen capacity (0.148 g/mL) greater than that of liquid hydrogen (0.070 g/mL) and a hydrogen mass storage capacity slightly exceeding 10 mass-%. The enthalpy of formation of AlH<sub>3</sub> is negative (−11.4 kJ/mol), but due to a positive entropy (30.04 J mol<sup>−1</sup> K<sup>−1</sup>), the equilibrium hydrogen pressure is 270 kbar at 298 K. The metastability of alane is generally attributed to a surface oxide layer that acts as a kinetic barrier to decomposition and protects the alane from the environment. There are at least seven AlH<sub>3</sub> polymorphic crystalline forms reported in the literature and except for the  $\alpha$  (the most stable), and  $\gamma$  phases, the crystal structures for the other phases remain unknown or are subject of dispute among the experts. Experiments showed that the thermal stability and ease of preparation of alane are strongly dependent upon purity of the reactants and reaction conditions. The presence of impurities or moisture affects strongly the thermal stability.

In order to obtain  $\alpha$ -AlH<sub>3</sub> with high purity, solid AlH<sub>3</sub>-etherate was synthesized and separated from the reaction mixture of LiAlH<sub>4</sub> and AlCl<sub>3</sub> in diethyl ether [343]. Then  $\alpha$ -AlH<sub>3</sub> with a purity of 99.5% was prepared via desolvation of the solid AlH<sub>3</sub>-etherate in toluene at 363 K (90 °C) for 2 h with the yield of 96.4%. The product was characterized by XRD, IR, elemental analysis, TGA/DSC, and SEM. The results indicated that the product had uniform crystallization, high purity, and good stability.

There are two possibilities to transform the etherate into the solid dry phase: **(1)** by heat treatment under vacuum or **(2)** by precipitation in an organic solvent [344]. With the heat treatment method at different temperatures, one obtains pure  $\gamma$ -AlH<sub>3</sub> and small crystallite  $\alpha$ -AlH<sub>3</sub> plus a small amount of  $\gamma$ -AlH<sub>3</sub> and traces of aluminum. With the solvent method at different crystallization temperatures, one obtains polymeric crystalline  $\alpha$ -AlH<sub>3</sub> plus  $\gamma'$ -AlH<sub>3</sub> (not identified) and traces of  $\epsilon$ -AlH<sub>3</sub>, polymeric crystalline  $\alpha$ -AlH<sub>3</sub> plus traces of  $\gamma'$ -AlH<sub>3</sub> (not identified) and traces of  $\epsilon$ -AlH<sub>3</sub> and a little pure polymeric crystalline  $\alpha$ -AlH<sub>3</sub>.

In analogy to the problems with obtaining an ether-free product with beryllium hydride, it is equally difficult to obtain a completely ether-free aluminum hydride. It has been attempted to improve the stability of AlH<sub>3</sub> by doping it with magnesium or magnesium hydride or lithium borohydride [345].  $\alpha$ -AlH<sub>3</sub> was synthesized in an inert solvent by desolvation of solid AlH<sub>3</sub>-etherate, which was obtained from the reaction of LiAlH<sub>4</sub> and AlCl<sub>3</sub> in ether. The effects of LiBH<sub>4</sub> addition, temperature and time, solvent, crystallizing agent in desolvation on the product were discussed. The optimum process conditions were as follows: the molar ratio of LiAlH<sub>4</sub> and AlCl<sub>3</sub> was 4:1, the solid AlH<sub>3</sub>-etherate was obtained by solvent removal in vacuum; the desolvation was conducted in toluene at 363 K (90 °C) for 2 h in the presence of crystallizing agent. In this process,  $\alpha$ -AlH<sub>3</sub> with cubic crystal shape and high stability was prepared with a purity of 96% and yield of 96.4%.

Aluminum hydride etherate has the molecular formula of  $\text{AlH}_3 \cdot 0.22\text{Et}_2\text{O}$ .  $\text{AlH}_3$ -etherate is first desolvated to  $\gamma\text{-AlH}_3$ , which immediately transforms into the  $\alpha$ -phase during the heating process. Excess  $\text{LiAlH}_4$  is essential to remove ether in the desolvation process. Three aluminum hydride polymorphs ( $\alpha\text{-AlH}_3$ ,  $\beta\text{-AlH}_3$ , and  $\gamma\text{-AlH}_3$ ) were prepared through the desolvation of  $\text{AlH}_3$ -etherate using the organometallic synthesis method and the structure and morphology of the samples were characterized using FTIR, SEM, and XRD [346]. The thermal properties of  $\text{AlH}_3$  polymorphs were experimentally investigated under transient heating and isothermal processes. The results suggested that the  $\alpha$ -polymorph is the most stable of the three polymorphs, and the decomposition of the less stable polymorphs,  $\beta\text{-AlH}_3$  and  $\gamma\text{-AlH}_3$ , typically occurs via an exothermic transformation to the  $\alpha$ -phase ( $\geq 100^\circ\text{C}$ ) followed by the decomposition of  $\alpha\text{-AlH}_3$  phase into Al and  $\text{H}_2$ ; however, a fraction of  $\gamma$  and  $\beta$ -polymorphs may decompose directly to Al and  $\text{H}_2$  at low temperatures ( $< 100^\circ\text{C}$ ). The direct decomposition of the  $\gamma$  and  $\beta$  phases is faster than that of the  $\alpha$  phase due to the lower total formation enthalpy.

Instead of ether as a solvent, the reaction can be carried out in aliphatic amines, leading to Lewis adducts of  $\text{AlH}_3$  as intermediates. This method can use the more economical lithium hydride instead of lithium aluminum hydride as a starting material [347]. At first, the dimethylethylamine-alane (DMEAA) was synthesized by reaction of LiH and  $\text{AlCl}_3$  with the participation of dimethylethylamine (DMEA). Then DMEAA and an excess of triethylamine (TEA) were transaminated giving triethylaminealane (TEAA). Finally,  $\text{AlH}_3$  was obtained by vacuum heating of TEAA. All intermediate and ultimate products were characterized by FT-IR, XRD, and TGA. The cost of  $\text{AlH}_3$  preparation could be reduced through switching to the economical LiH instead of  $\text{LiAlH}_4$ .

The electrolysis of sodium aluminum hydride in a nonpolar solvent gives aluminum hydride at the anode [348]. The anolyte solution slurry is then filtered to remove the alane.

To better understand the desorption properties of hydrogen in alane, thermodynamically stable  $\alpha\text{-AlH}_3$  was synthesized by employing an ether-solvent reaction method [349]. The dependence of pathways on phase formation and the properties of hydrogen evolution were investigated, and the results were compared with the ones for  $\gamma\text{-AlH}_3$ .  $\alpha\text{-AlH}_3$  was formed when the residue of the process, i.e.,  $(4\text{AlH}_3n[(\text{C}_2\text{H}_5)_2\text{O}] + \text{LiAlH}_4 + \text{LiBH}_4)$ , was heated at 353–363 K ( $80\text{--}90^\circ\text{C}$ ) for 4 h, while  $\gamma\text{-AlH}_3$  was obtained when the residue was heated at 333–343 K ( $60\text{--}70^\circ\text{C}$ ) for 3 h.

$\alpha$ -Alane can be made by reacting lithium aluminum hydride and aluminum chloride in a solvent to produce alane etherate, filtering alane etherate from the reactant, combining the filtered alane etherate with a lithium borohydride solution to produce microcrystalline alane etherate, removing remaining solvent from the solids, creating a slurry from the solids and an aromatic solvent, and heating the slurry to convert the microcrystalline alane etherate to microcrystalline alpha alane [350].

A method for forming an alane-etherate complex and  $\alpha$ -alane from the alane-etherate complex includes reacting an alkyl halide (*n*-butyl bromide) with a metal alanate (sodium aluminum hydride or lithium aluminum hydride) in a solvent (diethyl ether) [351]. A tertiary amine (trialkyl amine) may also be added to the reaction. The alane is collected after removal of the solvent and/or the tertiary amine.

It was attempted to produce a stable alane structure through a wet chemical synthesis process [352]. Initial dissolution of starting reactants in ether produced a consistent crystal structure (cubic shape) and elemental compositions analogous to the theoretical composition. The chemical structure, when examined by XRD, matched well with the standard reference  $\alpha$ -type alane, and the resulting particle size of the precipitated  $\alpha$ -type alane ranged from 7 to 13  $\mu\text{m}$ . A pivotal step in the alane synthesis was selective crystallization from the liquid phase alane-etherate  $\text{AlH}_3 \cdot (\text{Et}_2\text{O})_n$ , followed by acid treatment of the precipitated particulate alanes using an appropriately mixed solution. See also [353–355].

#### 10.2.2.1 Preparation of Aluminum Hydride without the Use of Solvents

The problem with ether as a solvent and solvate tenaciously adhering to  $\text{AlH}_3$  can be circumvented by solid-state ball-milling the two reactants anhydrous aluminum chloride with a metal hydride in the dry state under a hydrogen atmosphere. Many of the publications on this process fail to report the hydrogen pressure under which the reaction was carried out.

Alane can be synthesized by cryomilling alkali metal or alkaline earth metal alanates and aluminum halides [356]. The yield of alane has been found to be increased using  $3\text{NaAlH}_4 + \text{AlCl}_3$ . Furthermore, the relative amount of  $\alpha'$ - $\text{AlH}_3$  over  $\alpha$ - $\text{AlH}_3$  was increased from 0.63–0.67 to 1.05 by adding small amounts of  $\text{FeF}_3$  to  $3\text{LiAlH}_4 + \text{AlCl}_3$ . When synthesized from  $3\text{NaAlH}_4 + \text{AlCl}_3$  the ratio  $\alpha'/\alpha$  was increased to 1.04.  $\alpha'$ - $\text{AlH}_3$  was confirmed to be less thermally stable than  $\alpha$ - $\text{AlH}_3$ . The maximum amount of synthesized alane was obtained by using  $\text{NaAlH}_4$  as a starting material instead of  $\text{LiAlH}_4$ ; however, the synthesis route from  $\text{NaAlH}_4$  produced alane with less thermal stability than the synthesis from  $\text{LiAlH}_4$ . The use of  $\text{Na}_3\text{AlH}_6$ ,  $\text{LiH}$  or  $\text{TiCl}_3$  resulted in no alane formation.

A mechanochemical dry grinding synthesis process has been used to synthesize alane nanoparticles [357]. The alane was synthesized via a dry chemical reaction between lithium alanate ( $\text{LiAlH}_4$ ) and aluminum chloride ( $\text{AlCl}_3$ ) at room temperature within a ball mill and also at 77 K within a cryogenic mill. The reaction product formed consisted of alane nanoparticles embedded within a lithium chloride by-product phase. The  $\text{LiCl}$  was then washed with a solvent resulting in alane nanoparticles, which were separated from the by-product phase but are kinetically stabilized by an amorphous particle surface layer. The synthesis of a particular alane structural phase is largely dependent on the milling conditions and two major phases ( $\alpha$ ,  $\alpha'$ ) as well as two minor phases ( $\beta$ ,  $\gamma$ ) have been identified. Excessive ball-milling at room

temperature can provide enough energy to allow alane to release hydrogen gas and form aluminum metal nanoparticles, which is undesirable. A comparison between XRD and hydrogen desorption results suggested that a non-crystalline  $\text{AlH}_3$  phase may be present in the synthesized samples.

The problem with ether as a solvent and solvate tenaciously adhering to  $\text{AlH}_3$  is avoided by ball-milling the two reactants anhydrous aluminum chloride with lithium aluminum hydride in the dry state under a hydrogen atmosphere [358, 359]. The synthesis of  $\text{AlH}_3$  from  $\text{LiAlH}_4$  and  $\text{AlCl}_3$  can be performed by ball-milling solid phase chemical reaction under a hydrogen atmosphere, thus avoiding the use of solvents which might cling to the product. The effects of different milling times (4–20 h) on the solid-state chemical reaction and dehydrogenation properties of the milled mixture were investigated comprehensively using XRD, TGA-DSC, MS, SEM, and dehydrogenation measurements. The reaction

was almost complete after milling for 20 h and amorphous  $\text{AlH}_3$  was formed.

Many of the current synthesis methods for aluminum hydride involve reacting  $\text{AlCl}_3$  and  $\text{LiAlH}_4$  in solvents. The reaction requires the formation of an alane adduct such as  $\text{AlH}_3 \cdot [(\text{C}_2\text{H}_5)_2\text{O}]$  prior to obtaining crystallized stable  $\alpha\text{-AlH}_3$ . This process requires several hours of pumping in a vacuum system to remove the ether and convert the alane etherate into stable  $\alpha$ -alane. This crystallization process is both costly and hazardous because a large amount of highly flammable material (e.g. ether) is removed by vacuum pumps over several hours. A different method to synthesize adduct-free alane involved mixing  $\text{AlCl}_3$  and  $\text{LiAlH}_4$  in the solid state, heating to 348 K (75 °C) and only solvate-free  $\alpha\text{-AlH}_3$  was obtained [360]. The  $\alpha\text{-AlH}_3$  product can be washed with ether-free solvents leading to zero formation of alane adducts. In addition, the unwanted LiCl by-product can also be removed during the solvent wash, resulting in halide-free  $\alpha$ -alane. Although simply mixing and heating the powdered reactants led to a 40% yield of alane, having the reactants pre-compacted and mechanically pressed while heating increased the yield to 60% of crystalline  $\alpha\text{-AlH}_3$ .

Nearly quantitative mechanochemical synthesis of non-solvated  $\text{AlH}_3$  from lithium aluminum hydride ( $\text{LiAlH}_4$ ) and aluminum chloride ( $\text{AlCl}_3$ ) has been achieved at room temperature under reasonably low pressure of hydrogen (210 bar) or inert gas (125 bar for He or 90 bar for Ar) [361, 362]. XRD, solid-state  $^{27}\text{Al}$  NMR spectroscopy, and temperature programmed desorption (TPD) analyses of as-milled materials revealed a nearly complete conversion of a 3:1 (molar) mixture of  $\text{LiAlH}_4$  and  $\text{AlCl}_3$  to a 4:3 (molar) mixture of  $\text{AlH}_3$  and LiCl in ca. 30 min. By applying pressure of 210 bar or less (depending on the gas: hydrogen, helium or argon), competing reactions leading to formation of metallic aluminum can be completely suppressed. XRD and NMR analyses of products extracted at various stages of the mechanochemical reaction between  $\text{LiAlH}_4$  and  $\text{AlCl}_3$  revealed that the solid-state transformation proceeds with  $\text{LiAlCl}_4$  as an intermediate. Evidently, the critical

pressure required to suppress the formation of metallic aluminum depends on the rate at which mechanical energy is supplied during milling. For example, the critical pressure is reduced from 210 to 1 bar of hydrogen when the milling speed of a standard planetary mill is reduced from 300 to 150 rpm, although at the expense of sluggish kinetics and much longer reaction time.

A mechanochemical, solid-state reaction process for the synthesis of alane ( $\text{AlH}_3$ ) starting with lithium hydride and anhydrous aluminum chloride at room temperature and the underlying reaction pathway have been studied [363]. In contrast to a conventional process using the same two reactants dissolved in diethyl ether, this approach enables a solvent-free synthesis, thereby directly leading to adduct-free alane. The method is quick and efficient, resulting in the quantitative conversion of all aluminum in the starting mixture to alane. Both the intermediate compounds formed during the reaction and the final products have been characterized by powder XRD, solid-state  $^{27}\text{Al}$  NMR spectroscopy and temperature programmed desorption analysis of the as-milled mixtures. An excess of LiH in the starting mixture (with an optimal ratio of 9 LiH:1  $\text{AlCl}_3$ ) is essential for the formation and stability of Al–H bonds, initially in the form of alanates and, eventually, as alane. Further processing of this mixture, gradually adding  $\text{AlCl}_3$  to reach the ideal 3 LiH:1  $\text{AlCl}_3$  stoichiometry, appears to restrict the local accumulation of  $\text{AlCl}_3$  during the ball-milling process, thereby preventing the formation of unstable intermediates that decompose to metallic Al and molecular hydrogen. Under the milling conditions used, a hydrogen pressure of ca. 300 bar is required to suppress competing reactions that lead to the formation of metallic Al at room temperature.

Aluminum hydride has a high gravimetric hydrogen capacity (10.1 mass-%) and has attracted considerable attention due to its potential application for hydrogen storage. Most of the routes developed for the synthesis of  $\text{AlH}_3$  and regeneration of the aluminum metal residue are energy-consuming and economically impractical for mass production. Solid state reactive milling methods to synthesize  $\text{AlH}_3$  using aluminum chloride and cheap metal hydrides as starting reagents, such as LiH/ $\text{AlCl}_3$ ,  $\text{MgH}_2/\text{AlCl}_3$  or  $\text{CaH}_2/\text{AlCl}_3$  reaction systems are more promising. In addition to LiH, NaH,  $\text{LiAlH}_4$ , and  $\text{NaAlH}_4$ , also  $\text{MgH}_2$  can be used as the starting hydride for making  $\text{AlH}_3$  by a solid state reactive milling reaction [364, 365]. Based on SEM, TEM, and NMR analyses, an amorphous intermediate  $(\text{AlH}_6)_n$  was preferentially formed during the solid state reaction between  $\text{MgH}_2$  and  $\text{AlCl}_3$  and recrystallized as a  $\gamma$ -phase  $\text{AlH}_3$  at the final stage of the reaction. The reaction progress and products during reactive milling were characterized by XRD and  $^{27}\text{Al}$  NMR, and the morphology as well as the microstructure of the as-milled samples by SEM and TEM, respectively [366]. It was found that nano-sized  $\gamma$ - $\text{AlH}_3$  could be synthesized by reactive milling with commercial  $\text{AlCl}_3$  and nanocrystalline  $\text{MgH}_2$  as reagents.

Solid-state mechanochemical synthesis of alane starting from sodium hydride (NaH) and aluminum chloride at room temperature was achieved by a stepwise addition of  $\text{AlCl}_3$  to the initial reaction mixture that contained sodium hydride in excess

of stoichiometric amount [362, 367]. As in the case of previously investigated LiH-AlCl<sub>3</sub> system, complete selectivity was achieved whereby formation of unwanted elemental aluminum was fully suppressed, and AlH<sub>3</sub> was obtained in quantitative yield. Reaction progress during each step was investigated by means of solid-state NMR and powder XRD, which revealed that the overall reaction proceeds through a series of intermediate alانات that may be partially chlorinated. The NaH/AlCl<sub>3</sub> system presented some subtle differences compared to LiH/AlCl<sub>3</sub> system particularly with respect to optimal concentrations needed during one of the reaction stages. High local concentrations of NaH may stabilize chlorine-containing derivatives and prevent premature decomposition of AlH<sub>3</sub> into elemental aluminum with hydrogen evolution. Complete conversion with quantitative yield of alane was confirmed by both NMR and hydrogen desorption analysis.

Aluminum hydride can be prepared by thermal decomposition of triethylaluminum under mild hydrogen pressures (10 MPa) with the use of surfactants [368]. With tetraoctylammonium bromide, the synthesis led to the formation of nanosized AlH<sub>3</sub> with the known  $\alpha$ -phase, and these nanoparticles released hydrogen from 313 K (40 °C) and above instead of the 398 K (125 °C) observed with bulk  $\alpha$ -AlH<sub>3</sub>.

#### 10.2.2.2 Preparation of Aluminum Hydride by Direct Synthesis from the Elements

Aluminum hydride forms from the elements only under extreme pressure conditions. This is not an economic method for making aluminum hydride. The PT diagram for aluminum hydride at 0.5–6.5 GPa and 373–1073 K (100–700 °C) indicated that the decomposition of AlH<sub>3</sub> is reversed at high pressures [369]. The compound can be prepared from the elements at pressures above 2.5 GPa; however, synthesis of AlH<sub>3</sub> via the solid-state exchange reactions of LiAlH<sub>4</sub> or LiH with AlCl<sub>3</sub> under quasi-hydrostatic conditions with excess hydrogen is more advantageous. The synthetic PT condition diagram is limited by two straight lines that correspond to the decomposition of AlH<sub>3</sub> into elements and the phase transition  $\alpha$ -LiAlH<sub>4</sub>  $\rightarrow$   $\beta$ -LiAlH<sub>4</sub>. The reaction of AlCl<sub>3</sub> with LiH to give AlH<sub>3</sub> proceeds only at  $P > 5.6$  GPa and  $T > 823$  K ( $> 550$  °C). Only the most compact  $\alpha$  modification of AlH<sub>3</sub> is formed under these PT conditions.

The decomposition of solid aluminum hydride was carried out at 423 and 413 K (150 and 140 °C) and under high pressure of gaseous hydrogen [370]. Pressure plateaus were observed indicating an equilibrium between the hydride and gaseous hydrogen. The AlH<sub>3</sub> dissociation equilibrium kinetics were measured by recording the hydrogen pressure increase as a function of time.

The formation of aluminum hydride by bombarding a thin film of solid aluminum chloride with active (atomic) hydrogen from a plasma discharge can be catalyzed by finely divided palladium black [371]. This is not a reaction that would be economically feasible. It is only of academic interest.

The PT diagram of the hydrogen-aluminum system was determined for a pressure range of 0–10 GPa and a temperature range of 300–1073 K (27–800 °C) by *in situ* XRD

[372, 373]. Pristine aluminum was hydrogenated to trihydride at 8.9 GPa and 873 K (600 °C). The cyclic formation and decomposition of the hydride resulted in a more active porous material and lowering of the hydrogenation conditions down to 4.9 GPa and 603 K (330 °C). Transparent single crystals were recovered at ambient conditions after cooling and depressurization.

The direct synthesis of aluminum hydride from the elements would be a promising approach to make aluminum hydride more readily available but it is still far removed from industrialization [374]. Aluminum hydride can be prepared by direct hydrogenation of an aluminum/gallium alloy at pressures up to 103 MPa (15 kpsi) [375]. The mixture of aluminum hydride and gallium hydride is heated to decompose the thermally less stable gallium hydride, leaving the thermally more stable aluminum hydride behind, and the gallium metal is recycled.

Alane is difficult to synthesize directly from its elements. Using density functional theory, the defect-mediated formation of alane monomers on Al(111) single crystal metal surfaces in a two-step process was examined by computations: **(1)** dissociative adsorption of  $H_2$  and **(2)** alane formation, which are both endothermic on a clean surface [376]. Only with Ti dopant to facilitate  $H_2$  dissociation and vacancies to provide Al adatoms, both processes become exothermic. In agreement, *in situ* scanning tunneling microscopy showed that during  $H_2$  exposure, alane monomers and clusters form primarily in the vicinity of Al vacancies and Ti atoms. Moreover, ball-milling of the Al samples with Ti (providing necessary defects) showed a 10% conversion of Al into  $AlH_3$  or closely related species at 344 bar  $H_2$ , indicating that the predicted pathway may lead to the direct synthesis of alane from elements at pressures much lower than the 104 bar expected from bulk thermodynamics.

### 10.2.2.3 Stabilization of Aluminum Hydride

The rate of thermal decomposition and reactivity of aluminum hydride in air and with other propellant ingredients can be decreased by passivating or coating the freshly prepared hydride. Aging of magnesium-doped  $AlH_3$  has resulted in an approximate sevenfold improvement in hydride stability. The increased stability due to aging was found to increase as the magnesium concentration was increased [377].

Treatment for 5 days in *n*-butylamine (NBA) containing 2% water was recommended as the best procedure at that time for magnesium-doped aluminum hydride [378]. This treatment produced a material with good thermal stability (15–25 days to 0.1% decomposition at 333 K = 60 °C), a low oxygen content (0.1%), and it had a proven compatibility with high energy propellant ingredients. Scanning electron photomicrographs revealed the surface characteristics of aluminum hydride crystals and showed a thin coating, probably  $Al(OH)_3$ , generated by hydrolysis treatment. The coating thickness depended on the type of treatment, length of treatment, water content in the organic solvent, and original stability of the material. Treatment for 5 days in ethanol containing 2% water at 353 K (80 °C) produced aluminum hydride

with better thermal stability than the NBA method. The best samples required 35–40 days to reach 0.1% decomposition at 333 K (60 °C). Compatibility with TVOPA was worse and the increase in oxygen content was greater than for NBA-treated samples. Aluminum hydride hydrolyzes slowly in water buffered at pH 7. After drying, the hydride had an improved thermal stability and excellent compatibility with TVOPA and TEGDN. For a given amount of hydrolysis (measured by oxygen uptake during treatment), the increase in thermal stability at 333 or 353 K (60 or 80 °C) was poorer than the NBA or EtOH treatments. Aluminum hydride treated for 3 days in a pH 7 solution and followed by a 5-day treatment in ethanol containing 2% water at 353 K (80 °C) had a thermal stability comparable to the NBA-treated material. It has better compatibility with TVOPA than the latter, but oxygen uptake during the treatment was almost double (2 vs. 1%). The water which is in the solvents used for treatment is necessary for an improvement in thermal stability. Treatment in solvents with low water contents (<0.1%) resulted in a loss of stability or an exothermic reaction of the hydride with the organic solvent.

Soaking Mg-doped unsolvated  $\text{AlH}_3$  in a buffered solution of  $\text{KH}_2\text{PO}_4$  and NaOH at pH 6.8 for 15 min and drying under vacuum was supposed to result in a thermally more stable hydride [379].  $\text{AlH}_3$  can be stabilized by soaking it in an aqueous solution containing amines or hydrazine [380] or by doping it with magnesium from a solution of  $\text{MgCl}_2$  in an ether/benzene mixture [381].

Storing non-solvated crystalline  $\text{AlH}_3$  or Mg-doped  $\text{AlH}_3$  for at least 4 months under an inert atmosphere at low temperatures in the range of 258–73 K (–15 to –200 °C) was supposed to improve the thermal and storage stability of the hydride after it is brought back to room temperature [382]. In one example, samples of Mg-doped  $\text{AlH}_3$  with 2.1% Mg were held at 258 K for 75 days and 1.5 years. After thawing, samples heated to 333 K (60 °C) took 75 and 93 days, respectively, to reach 1% decomposition, while an untreated reference sample reached 1% decomposition in only 13 days. Adsorbing of up to 1% nitric oxide at  $10^{-5}$  mm Hg pressure for 16 h onto the surface of  $\text{AlH}_3$  was supposed to improve thermal stability and compatibility with other propellants [383]. The treated sample, when heated to 373 K (100 °C) for 4 or 7 h, decomposed to an extent of 0.1 and 0.2%, respectively, while an untreated sample was 0.6 and 5.6% decomposed under the same conditions.

In a method for preparing non-solvated alane, alane-etherate may be desolvated in the presence of a small amount of lithium aluminum hydride [330, 384]. The combination of  $\text{LiBH}_4/\text{LiAlH}_4$  enables use of a lower processing temperature, and  $\alpha$ -alane is the final product after heating at 338 K (65 °C) under vacuum.

Alane can be stabilized by treating  $\alpha$ - $\text{AlH}_3$  with an acidic solution that contains a stabilizing agent such as an electron donor, an electron acceptor, or a compound such as 8-hydroxyquinoline which coordinates the  $\text{Al}^{3+}$  ion [385–388].

A crystallization additive (e.g., squalene, norbornylene, norbornadiene, dimethyl anisole) added to an alane-ether complex solution or to an aqueous ether/alane-ether

complex solution may result in more uniform crystals of  $\alpha$ -AlH<sub>3</sub> [389, 390]. Ether is then removed from the crystallization solution to crystallize the stabilized  $\alpha$ -alane. See also [391].

#### 10.2.2.4 Coatings for Aluminum Hydride

The main disadvantage for the application of AlH<sub>3</sub> as an ingredient in propellants is its sensitivity towards oxidation, and hydrolysis. Stabilization by additives or coatings is required to ensure the safe handling of AlH<sub>3</sub>.

Coatings with alkyl cyanides such as acrylonitrile or propionitrile make aluminum hydride more compatible with other rocket propellant ingredients [392]. Acrylonitrile-coated AlH<sub>3</sub> had a much better compatibility with trimethylolethane trinitrate as indicated by sharply reduced gas evolution of the mix during storage. Coating with stearic acid offers some protection of  $\alpha$ -AlH<sub>3</sub> particles [393]. Coating aluminum hydride with nitrocellulose (NC) has the advantage that the nitrocellulose contributes to the performance of solid rocket propellants using these NC-coated AlH<sub>3</sub> particles [394].

A detailed characterization of a stabilized sample of aluminum hydride was performed and different stabilization concepts were tested [395]. An effective stabilization mechanism was achieved by a protective coating with aluminum hydroxide clusters.

Liquid carbon dioxide can be used as an anti-solvent, dispersant, drying medium and inert fluid for coating aluminum hydride [396]. Alane samples coated from a suspension in liquid carbon dioxide were characterized by SEM, XPS, XRD, and FT-IR. The coating agent was uniformly applied on the surface of alane and the crystalline phase remained unchanged. The thermal stability of alane before and after coating was analyzed by DSC, indicating improved thermal stability. The lower electric spark sensitivity of the coated alane improved safety, serviceability and stability of this material.

Once it is exposed to air, the surface of alane is widely believed to consist of an aluminum oxide layer, which is expected to exhibit different reactivity toward organic polymer coating molecules than the native aluminum hydride surface. Microscale  $\alpha$ -AlH<sub>3</sub> particles were passivated by nanometer Al<sub>2</sub>O<sub>3</sub> layers via atomic layer deposition [397]. Conformal amorphous Al<sub>2</sub>O<sub>3</sub> films were coated around the crystalline  $\alpha$ -AlH<sub>3</sub> particles, serving as physical barriers to prevent reactions with air or moisture. If used as a hydrogen storage medium, the dehydrogenation speed of passivated AlH<sub>3</sub> particles was about the same as that of untreated samples.

#### 10.2.3 Physical Properties of Aluminum Hydride

It is difficult to obtain a complete, consistent set of physical properties for aluminum hydride, because the material is often contaminated with solvents and may exist in several polymorphic modifications. Physical properties of aluminum hydride are summarized in Table 17. See also [398, 399].

**Table 17:** Physical properties of  $\alpha$ -aluminum hydride.

| Property              | SI units               | Other units                | References |
|-----------------------|------------------------|----------------------------|------------|
| Molecular mass        | 30.00536 g/mol         | 33.33 mol/kg               | [10]       |
| Density               | 1.43 g/cm <sup>3</sup> | —                          | [208]      |
|                       | 1.43 g/cm <sup>3</sup> | 0.0516 lb/in. <sup>3</sup> | [286]      |
| Enthalpy of formation | −11.55 kJ/mol          | −92 cal/g = −2.76 kcal/mol | [286]      |

### 10.2.3.1 Molecular Structure of Aluminum Hydride

Alane is a polymer structure with hydrogen bridges and its formula should be written  $(\text{AlH}_3)_n$ . There are at least seven different  $\text{AlH}_3$  solid phases described in the literature but only the most stable  $\alpha$ - $\text{AlH}_3$  polymorph with an enthalpy of formation of  $\Delta H_f^\circ = -11.4 \text{ kJ/mol}$  can be a candidate for propellant utilization. Aluminum hydride exists in several polymorphs, which are named  $\alpha$ -alane,  $\alpha'$ -alane,  $\beta$ -alane,  $\delta$ -alane,  $\varepsilon$ -alane,  $\theta$ -alane, and  $\gamma$ -alane.  $\alpha$ -Alane has a cubic or rhombohedral crystal morphology, whereas  $\alpha'$ -alane forms needle-like crystals and  $\gamma$ -alane forms a bundle of fused needles. Alane is soluble in THF and diethyl ether.

The structure of  $\alpha$ -alane consists of aluminum atoms which are surrounded by six hydrogen atoms that bridge to six other aluminum atoms. Alane phases have been prepared by desolvating the alane etherate and several solid-state NMR techniques have been used to characterize various  $\text{AlH}_3$  samples. NMR spectra for the  $^1\text{H}$  and  $^{27}\text{Al}$  nuclei have been obtained on a variety of  $\text{AlH}_3$  samples that include the  $\beta$ - and  $\gamma$ -phases as well as the most stable  $\alpha$ -phase [400, 401]. Direct decomposition of the  $\gamma$ - $\text{AlH}_3$  to aluminum metal at room temperature was unambiguously confirmed by these NMR studies.

Aluminum hydride has been evaluated as a hydrogen storage medium. The thermodynamic and spectroscopic properties of  $\text{AlH}_3$ , were measured, in particular those of the  $\alpha$ ,  $\alpha'$ , and  $\gamma$  polymorphs, of which  $\alpha'$ - $\text{AlH}_3$  is characterized in more detail, and free from traces of other polymorphs or side products [402, 403]. All three polymorphs were investigated by  $^1\text{H}$  magic-angle spinning (MAS)-NMR spectroscopy, and their  $^{27}\text{Al}$  MAS-NMR spectra were measured and compared with literature data. The etherate  $\text{AlH}_3 \cdot n\text{Et}_2\text{O}$  was studied by  $^1\text{H}$  and  $^{27}\text{Al}$  MAS-NMR spectroscopy and DSC and TGA methods, and an accurate decomposition pathway has been established for this adduct.

While the dominant components in these NMR spectra correspond to the aluminum hydride phases, other species were found that include Al metal, molecular dihydrogen ( $\text{H}_2$ ), as well as peaks that can be assigned to Al-O species in different configurations. The occurrence and concentration of these extraneous components are dependent upon the initial  $\text{AlH}_3$  phase composition and preparation procedures. Both the  $\beta$ - $\text{AlH}_3$  and  $\gamma$ - $\text{AlH}_3$  phases were found to generate substantial amounts of Al

metal when the materials were stored at room temperature while the  $\alpha$ -phase materials do not exhibit these changes.

Alane has been subjected to Raman studies under static compression to see if there were any phase changes [404]. The Raman spectra showed four modes, which increased in frequency as pressure was increased from ambient to 6.6 GPa. From the pressure dependence, the pressure coefficient for each mode has been estimated and used to evaluate the Grueneisen parameters. Infrared spectra were also collected under ambient pressure condition for alane polymorphs.

Alane, crystallizing in the  $\gamma$ - $\text{AlH}_3$  polymorphic modification, was synthesized and then structurally characterized by means of synchrotron X-ray powder diffraction [405].  $\gamma$ - $\text{AlH}_3$  crystallized with an orthorhombic unit cell (space group  $Pnmm$ ,  $a = 5.3806(1) \text{ \AA}$ ,  $b = 7.3555(2) \text{ \AA}$ ,  $c = 5.77509(5) \text{ \AA}$ ). The crystal structure of  $\gamma$ - $\text{AlH}_3$  contains two types of  $\text{AlH}_6$  octahedra as the building blocks. The Al–H bond distances in the structure vary in the range of 1.66–1.79  $\text{\AA}$ . A prominent feature of the crystal structure is the formation of the bifurcated double-bridge bonds,  $\text{Al}\cdots 2\text{H}\cdots\text{Al}$ , in addition to the normal bridge bonds,  $\text{Al}-\text{H}-\text{Al}$ . The geometry of the double-bridge bond showed formation of short Al–Al (2.606  $\text{\AA}$ ) and Al–H (1.68–1.70  $\text{\AA}$ ) bonds compared to the Al–Al distances in Al metal (2.86  $\text{\AA}$ ) and Al–H distances for Al atoms involved in the formation of normal bridge bonds (1.769–1.784  $\text{\AA}$ ). The crystal structure of  $\gamma$ - $\text{AlH}_3$  contains large cavities between the  $\text{AlH}_6$  octahedra. As a consequence, the density is 11% less than for  $\alpha$ - $\text{AlH}_3$ .

Although a multitude of boron hydrides are known, the aluminum hydride chemistry is limited to very few examples such as  $\text{AlH}_3$ , its dimer and its polymeric form. In view of experimental studies on the possible existence of higher aluminum hydrides, a systematic theoretical study of the electronic structure and properties of these aluminum hydrides studied different classes of hydrides, viz., closo ( $\text{Al}_n\text{H}_{n+2}$ ), nido ( $\text{Al}_n\text{H}_{n+4}$ ), and arachno ( $\text{Al}_n\text{H}_{n+6}$ ) (Figure 3), similar to the boranes [406]. All the aluminum hydrides were predicted to have exceptionally large highest-occupied molecular orbital lowest-unoccupied molecular orbital gaps, low electron affinities, large ionization potentials, high symmetries and also large enthalpy and free energy of atomization. These exceptional properties can be indicative of the pronounced stability, and hence, it was expected that other aluminum hydride complexes can indeed be observed experimentally at some time in the future.

In order to resolve a contradiction between early theoretical prediction and experiments concerning the  $\gamma \rightarrow \alpha$  phase transition of aluminum hydride, computer models of Li-doped  $\text{AlH}_3$  were constructed and investigated theoretically [407]. Thermodynamic calculations showed that the  $\gamma \rightarrow \alpha$  transition of pure  $\text{AlH}_3$  absorbs energy, and the changes in Gibbs free energy are in the range of 1.74–1.99 kJ/mol at 298–380 K. These are opposite to the experimental fact that the  $\gamma$ - to  $\alpha$ -phase transition takes place at 380 K; however, the changes in enthalpy and Gibbs free energy in the  $\gamma \rightarrow \alpha$  phase transition of Li-doped  $\text{AlH}_3$  are negative. The doping of Li decreases the activation energy of the  $\gamma \rightarrow \alpha$  transition and introduces more metastable states between them.

### 10.2.3.2 Crystal Structure of Aluminum Hydride

SEM micrographs of  $\text{AlH}_3$  crystals taken at various laboratories show mainly monocrystalline particles in the size range 1–20  $\mu\text{m}$ , with irregular structure having crystalline edges ([408]; Figure 4). Structural analyses revealed the presence of a unique crystalline phase ( $\alpha\text{-AlH}_3$ ) with very large crystalline domains of 730 nm. The high purity and quality of these crystals seems the key factor for the overall excellent properties shown by the tested material.

The most stable structure of aluminum hydride is believed to be a hexagonal symmetry. Density functional theory calculations have identified two additional stable structures for  $\text{AlH}_3$  with cubic and orthorhombic symmetries [409]. Based on

**Figure 4:** SEM micrographs of  $\text{AlH}_3$  crystals (reprinted from [408] with permission from Dr. L. T. DeLuca 9 May 2021)

Legend: Magnification (a) 500X; (b) 10000X; (c) 300X; (d) 1000X

the quasi-harmonic approximation, the cubic and orthorhombic  $\text{AlH}_3$  are almost degenerate when the zero-point energies are included. The geometric and electronic structures, the phonon, and the thermodynamic properties for the hexagonal, cubic, and orthorhombic  $\text{AlH}_3$  have been studied by means of density functional theory and direct *ab initio* force constant approaches. The calculated electronic structures, phonon density of states, and thermodynamic functions for the three hydrides were similar. The results showed that these three hydrides have negative enthalpies of formation, but positive free energies of formation. The thermodynamic properties indicate that the orthorhombic and cubic  $\text{AlH}_3$  should be more difficult to dissociate than the hexagonal  $\text{AlH}_3$ .

X-ray diffraction confirmed the hexagonal unit cell and lattice parameters  $a = 4.447 \text{ \AA}$ ,  $c = 1.81 \text{ \AA}$  at 433 K immediately before decomposition [410]. X-ray and neutron powder diffraction data for aluminum hydride,  $\text{AlH}_3$ , and aluminum deuteride,  $\text{AlD}_3$ , were used to resolve these structures [411]. Both compounds crystallize in the trigonal space group  $R\bar{3}c$  with six molecules in a hexagonal unit cell of dimensions  $a = 4.449 \text{ \AA}$  and  $c = 11.804 \text{ \AA}$  for the hydride and  $a = 4.431 \text{ \AA}$  and  $c = 11.774 \text{ \AA}$  for the deuteride. Columns of Al atoms and spirals of H atoms are parallel with the  $c$  axis and are packed so that the Al has octahedral coordination symmetry. The closest  $\text{Al}\cdots\text{Al}$  distance is  $3.24 \text{ \AA}$ . The alternating planes of Al and H atoms perpendicular to the  $c$  axis, result in a stable structure which is a three-dimensional network of  $\text{Al}\cdots\text{H}\cdots\text{Al}$  bridges and is consistent with the observed high density of the crystal. The structure of  $\alpha\text{-AlH}_3$  shows that the corners of the hexagonal unit cell are formed of  $\text{AlH}_6$  octahedra, whereas hydrogen bridges connect two octahedra to each other. The unit cell of  $\text{AlH}_3$  is composed of atoms of aluminum (Al) and hydrogen (H) linked by single bonds of different distances:  $1.715 \text{ \AA}$  ( $\text{Al-H}$ ),  $2.418 \text{ \AA}$  ( $\text{H}\cdots\text{H}$ ) and  $3.236 \text{ \AA}$  ( $\text{Al}\cdots\text{Al}$ ) and a unit cell volume of  $33.5 \text{ \AA}^3$  per  $\text{AlH}_3$  unit cell.

In situ isothermal high-pressure synchrotron XRD and optical Raman spectroscopy were used to examine the structural properties, equation of state and vibrational dynamics of  $\alpha$ -aluminum hydride [412]. The X-ray measurements showed that the pressure-volume relations remain smooth up to pressures near 50 GPa. Although there was no evidence for a first-order phase transition, the unit cell axial ratio ( $c/a$ ) was anomalous near 2.5 GPa, which corresponded to the onset of a monoclinic structural distortion. Infrared measurements conducted within a similar pressure range showed a distinct discontinuity in the frequencies of the  $\text{Al-H}$  lattice modes. The combined data provided evidence for a monoclinic structural distortion beginning near 2.5 GPa. All structural changes were reversible upon pressure release.

### 10.2.3.3 Dimers and Polymers of Aluminum Hydride

Looking at the tendency of borane  $\text{BH}_3$  to form dimers like diborane  $\text{H}_2\text{BH}_2\text{BH}_2$ , one wonders if the same dimer-forming behavior and hydrogen bridging can be found with its higher analog,  $\text{AlH}_3$  [413]. The binding energy of dialane,  $\text{Al}_2\text{H}_6$ , has been measured

using mass spectrometric techniques to be  $138 \pm 21$  kJ/mol ( $33 \pm 5$  kcal/mol) [414]. This represented the first measurement of the thermochemical properties of dialane, which has only been observed in low-temperature matrices. High-level quantum mechanical calculations gave a binding energy in agreement with the measured value. Experimental and quantum mechanical calculations showed that dialane,  $\text{Al}_2\text{H}_6$ , is chemically similar to diborane,  $\text{B}_2\text{H}_6$ , even though the bonding for these two systems shows significant differences. Calculations revealed that the  $\text{Al}_6\text{H}_{18}$  cluster, with its hexa-coordination of the Al atoms, resembles the unit-cell of  $\gamma\text{-AlH}_3$ , thus  $\text{Al}_6\text{H}_{18}$  is a building block from which  $\gamma\text{-AlH}_3$  is formed [415].

Although many volatile binary boron hydride compounds are known, binary aluminum hydride chemistry is limited to the polymeric  $(\text{AlH}_3)_n$  solid. The reaction of laser-ablated aluminum atoms and pure  $\text{H}_2$  during co-deposition at 3.5 K, followed by UV irradiation and annealing to 6.5 K, allows dimerization of the intermediate  $\text{AlH}_3$  product to form  $\text{Al}_2\text{H}_6$  in a matrix of frozen hydrogen [416]. The  $\text{Al}_2\text{H}_6$  molecule was identified by seven new IR absorptions that were accurately predicted by quantum chemical calculations for dibridged  $\text{Al}_2\text{H}_6$ , a molecule that is isostructural with diborane.

Seven new absorptions for  $\text{Al}_2\text{H}_6$  were found in the IR spectrum of the solid hydrogen matrix sample [417]. These frequencies included terminal  $\text{Al-H}_2$  and bridge  $\text{Al-H-Al}$  stretching and  $\text{AlH}_2$  bending modes, which were accurately predicted by quantum chemical calculations for dibridged  $\text{Al}_2\text{H}_6$ , a molecule isostructural with diborane. Annealing these samples to remove the  $\text{H}_2$  matrix decreased the sharp  $\text{AlH}_3$  and  $\text{Al}_2\text{H}_6$  absorptions and formed broad  $1720 \pm 20$  and  $720 \pm 20$   $\text{cm}^{-1}$  bands, which are due to solid  $(\text{AlH}_3)_n$ . New absorptions were assigned to the  $\text{Al}_2\text{H}_5$  radical with a dibridged structure [418].

While boron forms many different hydrides, aluminum has been able to form only a few. A combined anion photoelectron and density functional theory computational study of the  $\text{Al}_4\text{H}_6^-$  anion and its corresponding neutral molecule,  $\text{Al}_4\text{H}_6$ , suggested that it may be a borane analog [419]. The data supported an  $\text{Al}_4\text{H}_6$  structure with a distorted tetrahedral aluminum atom framework, four terminal  $\text{Al-H}$  bonds, and two sets of counter-positioned  $\text{Al}\cdots\text{H}\cdots\text{Al}$  bridging bonds. The large gap between the highest occupied and the lowest unoccupied molecular orbitals found for  $\text{Al}_4\text{H}_6$ , together with its exceptionally high heat of combustion, further suggested that  $\text{Al}_4\text{H}_6$  may be an important energetic material **if** it can be prepared in bulk.

Aluminum hydride anion clusters,  $\text{Al}_n\text{H}_m^-$  ( $4 \leq n \leq 8$ ;  $0 \leq m \leq 10$ ) were studied by anion photoelectron spectroscopy and density functional theory [420] (Figure 5). Photoelectron spectra revealed that  $\text{Al}_4\text{H}_4$ ,  $\text{Al}_4\text{H}_6$ , and a family of species with general formula  $\text{Al}_n\text{H}_{n+2}$  ( $5 \leq n \leq 8$ ) have small adiabatic electron affinities and large HOMO-LUMO gaps (ranging from 0.5 to 1.9 eV) relative to those of their stoichiometric neighbors, possibly giving hope for their enhanced stabilities. DFT calculations showed that the  $\text{Al}_n\text{H}_{n+2}$  ( $5 \leq n \leq 8$ ) family adopts  $n$ -vertex polyhedral closo-structures with two extra hydrogen atoms occupying opposite bridging positions in agreement with Wade's

**Figure 5:** Molecular structure of theoretical higher aluminum hydrides (reprinted from [420], with permission from ©2007 American Chemical Society; permission conveyed through RightsLink.)

rule. These can be viewed as aluminum analog versions of hypothetical diprotonated closo-borane dianions ( $B_nH_n^{2-} + 2H^+$ ).  $Al_4H_4$  assumes a closo-tetrahedral geometry, while  $Al_4H_6$  takes on a distorted tetrahedral ( $D_{2d}$ ) structure with two counterpositioned bridging hydrogen atoms and had the largest HOMO-LUMO gap (1.9 eV) of all the alanes studied. All these studies on higher aluminum hydrides may be interesting from an academic point of view, but they will unfortunately not immediately lead to improved rocket propellants.

#### 10.2.3.4 Thermodynamic Properties of Aluminum Hydride

The enthalpy of formation and absolute entropy of solid  $AlH_3$  at 298 K have been measured as  $-11.4 \pm 0.8$  kJ/mol ( $-2.73 \pm 0.20$  kcal/mol) and  $30.0 \pm 0.4$  J mol $^{-1}$  K $^{-1}$  ( $7.18 \pm 0.10$  cal mol $^{-1}$  °C $^{-1}$ ), respectively [421]. The derived Gibbs energy of formation at 298 K of  $46.5 \pm 1.0$  kJ/mol ( $11.11 \pm 0.23$  kcal/mol) indicated that  $AlH_3$  is unstable at room temperature with respect to decomposition into its elements.

The phase change thermodynamics and molecular structures of the  $\alpha$ ,  $\beta$ , and  $\gamma$  polymorphs of  $AlH_3$  were determined using DSC and *ex situ* XRD [422]. The results demonstrated that at around 373 K (100 °C) the decomposition of the  $\beta$  and  $\gamma$  polymorphs occurred by an initial phase transition to the  $\alpha$  polymorph, followed by decomposition of the  $\alpha$  phase. The total heat evolved during the  $\beta \rightarrow \alpha$  transition was  $1.5 \pm 0.4$  kJ/mol and  $2.8 \pm 0.4$  kJ/mol during the  $\gamma \rightarrow \alpha$  transition. The transformation to the  $\alpha$ -phase is exothermic and is therefore likely to occur spontaneously at room temperature. A formation enthalpy of approximately  $-10$  kJ/mol was measured for  $\alpha$ - $AlH_3$ , which was in good agreement with previous experimental and calculated results.

Several polymorphs of  $AlH_3$  were prepared by organometallic synthesis and subjected to controlled decomposition to evaluate them as hydrogen storage media [423, 424]. It was shown that freshly synthesized, non-solvated  $AlH_3$  releases approximately 10 mass-%  $H_2$  at desorption temperatures less than 373 K (100 °C). The decomposition kinetics, measured by isothermal hydrogen desorption between 303 and 413 K (30 and 140 °C), suggested that the rate of  $H_2$  evolution is limited by nucleation and growth of

the aluminum phase. The decomposition thermodynamics were measured using DSC and ex situ XRD. The decomposition of the less stable polymorph,  $\gamma$ - $\text{AlH}_3$ , occurred by an exothermic transformation to the  $\alpha$  phase ( $\sim 100^\circ\text{C}$ ) followed by the decomposition of  $\alpha$ - $\text{AlH}_3$ . The enthalpy of formation of approximately  $-10\text{ kJ/mol}$  of  $\alpha$ - $\text{AlH}_3$  was confirmed, in good agreement with previously reported values.

## 10.2.4 Chemical Properties of Aluminum Hydride

### 10.2.4.1 Thermal Stability and Decomposition of Aluminum Hydride

Quite often, attempts to isolate the non-solvated form of alane from the ether solution result in the decomposition of the complex to aluminum and hydrogen [425]. Six of the seven known polymorphs of solid aluminum hydride will dehydrogenate on their own at room temperature over a period of hours or days. Only  $\alpha$ - $\text{AlH}_3$  is stable enough at room temperature to be considered as a rocket propellant ingredient.

The flash-pyrolytic decomposition of  $\text{AlH}_3$  has been studied by kinetic spectroscopy at  $2477 \pm 20\text{ K}$  [303]. The major dissociation product seen in the flash pyrolysis of  $\text{AlH}_3$  was  $\text{AlH}$ . The existence of a subhydride  $\text{AlH}_2$  was postulated, and its role in the pyrolytic decomposition of  $\text{AlH}_3$  was correlated to the already observed species  $\text{AlH}$ .

Metallographic studies showed that decomposition of  $\text{AlH}_3$  occurs throughout the crystal, particularly at discontinuities, such as voids, cracks, and grain boundaries [378]. Ion probe mass spectrometry showed a higher lithium content near the surface than in the interior of the crystals. Lithium aluminum hydride was extracted from  $\text{AlH}_3$  and is believed to be responsible for nucleation sites which result in the decomposition of  $\text{AlH}_3$ .

The thermal stability of three different samples of  $\text{AlH}_3$  was tested at 298, 313, 333 or 353 K (25, 40, 60 or  $80^\circ\text{C}$ ) [318]. Three different samples were studied: Lot 07035 (untreated), Lot 11236 (Mg-doped) and Lot 11177B (Mg-doped, DPA-treated and hydrolyzed, pH 7). There was a distinct difference in thermal stability between the three samples, with Lot 11177B being significantly better than either of the others. Hydrogen was observed from Lot 11177B only at 353 K ( $80^\circ\text{C}$ ) after 15 days. These samples showed no detectable decomposition after 30 days at 333 K ( $60^\circ\text{C}$ ) and about 3% decomposition after 72 days at 333 K ( $60^\circ\text{C}$ ). Investigators at Dow observed approximately 1% decomposition of  $\text{AlH}_3$  (Lot 11177B) in 30 days at 333 K ( $60^\circ\text{C}$ ). It is generally agreed that  $\text{AlH}_3$  decomposes autocatalytically. The induction period associated with the decomposition was observed by Dow to vary significantly from sample to sample. A combination of the autocatalytic process, the poorly defined induction period and sample to sample variations all contributed to variations in these results reported by different laboratories. Based on these results, all compatibility studies were conducted using Lot 11177B. When the sample was heated from ambient to 413 K ( $140^\circ\text{C}$ ), hydrogen constituted approximately 90% of the evolved gases. See also [425].

The temperature-dependent rate constants of aluminum hydride decomposition were determined by measuring the rate of isothermal hydrogen evolution between 333 and 413 K (60 and 140 °C) [426]. If aluminum hydride is intended as a reversible hydrogen storage medium for automobiles, it would be important to accelerate the decomposition and hydrogen release reaction. Particle size control and doping of  $\text{AlH}_3$  with small levels of alkali-metal hydrides (e.g.  $\text{LiH}$ ) results in accelerated desorption rates [427].

Decomposition kinetics of aluminum hydride were determined from gravimetric TGA data and volumetric vacuum thermal stability (VTS) results [428–430]. Chemical analysis showed the fresh samples had 88.30% (by mass) aluminum and 9.96% hydrogen. The average density, as measured by helium pycnometry, was  $1.486 \text{ g/cm}^3$ . Scanning electron microscopy showed that the particles were mostly composed of sharp-edged crystallographic polyhedra such as simple cubes, cubic octahedrons and hexagonal prisms. The decomposition kinetics of alane in argon atmosphere were examined by TGA to shed light on the mechanism of alane decomposition. Two kinetic models were successfully developed and used to propose a mechanism for the complete decomposition of alane and to predict its shelf life during storage. Alane decomposes in two steps: The slowest (rate-determining) step is solely controlled by solid-state nucleation of aluminum crystals. The fastest step is due to growth of the crystals. Thus, during decomposition, hydrogen gas is liberated and the initial polyhedral  $\text{AlH}_3$  crystals yield a final mix of amorphous aluminum and aluminum crystals. After establishing the kinetic model, prediction calculations indicated that alane can be stored in inert atmosphere at temperatures below 263 K (10 °C) for long periods of time (e.g., 15 years) without significant decomposition. After 15 years of storage, the kinetic model predicts ~0.1% decomposition, but storage at higher temperatures (e.g. 303 K = 30 °C) is not recommended.

The intrinsic and mechanically modified (ball-milled) thermal stabilities of the  $\alpha$ ,  $\beta$ , and  $\gamma$  phases of  $\text{AlH}_3$  have been experimentally determined [431]. The TGA profiles of the  $\alpha$  and  $\gamma$  phases exhibited dehydriding reactions in the temperature range of 370–450 K. The amounts of hydrogen released were nearly 9 mass-%. The profile of the  $\beta$  phase showed continuous dehydriding reactions, which differed from the other two phases. The values of the enthalpy of dehydriding reactions  $\Delta H_{\text{dehyd}}$  were determined to be  $6.0 \pm 1.5$ ,  $-3$  to  $-5$ , and  $1.0 \pm 0.5 \text{ kJ/mol H}_2$  for the  $\alpha$ ,  $\beta$ , and  $\gamma$  phases, respectively. The milling time dependences of the powder XRD measurement and thermal analyses indicated the occurrence of dehydriding reactions both in the  $\alpha$  and  $\gamma$  phases during ball-milling, but there was no drastic change in the  $\beta$  phase.

Alane splits completely into hydrogen and aluminum on heating at temperatures between 433 and 533 K depending on the heating rate. This reaction is of interest for hydrogen storage methods [432]. This endothermic process was observed with DSC and TGA, *in situ* XRD under argon and the residual crystallites were imaged by SEM (Figure 6). On dehydrogenation a nanostructured porous Al material emerges with

**Figure 6:** Decomposition of aluminum hydride (reprinted from [408] with permission of Dr. L. T. DeLuca 9-May-2021)

Legend: (a)  $\text{AlH}_3$  crystals before pyrolysis test at ICT; (b) porous structure after decomposition at 200 °C; (c) porous structure after decomposition at 400 °C; (d) amorphous Al in a pyrolysis furnace

specific surfaces up to 15–20 m<sup>2</sup>/g. The cuboid particles maintain their external shape while porosity develops in their internal shape [433, 434]. Similar tests then studied the oxidation of dehydrided particles in air [410, 435]. A thermal explosion risk may arise from a subsequent sudden Al oxidation of nanostructured, pyrophoric porous aluminum bodies as soon as they are exposed to air. If  $\text{AlH}_3$  is ever used as a hydrogen storage medium and the dehydrided porous Al, such as in the tank of an air/ $\text{H}_2$  fuel-cell powered automobile, is accidentally exposed to air, a fire hazard may result [436]. On dehydrogenation of  $\text{AlH}_3$ , a nanostructured pyrophoric Al material emerges with specific surfaces up to 15–20 m<sup>2</sup>/g. The surface areas depend on the heating rate because of a temperature-dependent crystallite growth. The resulting Al oxidizes up to 20–25% weight on air access forming an alumina passivation layer of 3–4 nm thickness on all exposed surfaces. The heat released from this Al oxidation induces a high risk to this type of hydrogen storage if the containment vessel might be accidentally destroyed. The kinetics of the dehydrogenation and the subsequent oxidation were investigated by thermal analysis. A reaction scheme was confirmed which consisted of a starting Avrami–Erofeev mechanism followed by formal 1st order oxidation on unlimited air access. The kinetic parameters, activation energies and pre-exponentials were evaluated and can be used to calculate the reaction progress and heat release rate.

Dehydrogenation precedes the burning of aluminum hydride in solid or hybrid rocket propellants at elevated pressures [437, 438]. The decomposition rate of aluminum hydride powder was measured at slightly elevated temperatures (400–500 K) using the pressure rise due to the released hydrogen [439]. The information is useful for understanding the combustion behavior of aluminum hydride when used in solid or hybrid rocket propellants. The thermolysis measurements fit well to an Arrhenius-type exponential fit, with a pre-exponential of  $3.29 \times 10^9 \text{ s}^{-1}$  and an activation energy of 97.6 kJ/mol.

The thermal decomposition of two polymorphs,  $\alpha\text{-AlH}_3$  and  $\gamma\text{-AlH}_3$ , was investigated by synchrotron XRD and thermal desorption spectroscopy (TDS) [440]. Activation energies, anisotropic volume expansions, and phase transformation paths were followed. The crystal structure data, including structure of hydrogen sublattice, and small charge transfer from the aluminum towards the hydrogen sites were observed during this high-resolution XRD study of  $\alpha\text{-AlH}_3$ .

$\alpha\text{-AlH}_3$  that was synthesized from  $\text{LiAlH}_4$  and  $\text{AlCl}_3$  was characterized by XRD and SEM and the thermal decomposition was investigated by TGA/DTG-DSC [441]. The kinetic parameters of the major decomposition reaction were calculated. The decomposition reaction kinetics of  $\alpha\text{-AlH}_3$  agreed with a nuclei production and nuclei growth model. The apparent activation energy, pre-exponential factor and mechanism function of the decomposition reaction of  $\alpha\text{-AlH}_3$  were  $E_a = 110.89 \text{ kJ/mol}$ ,  $\ln A = 26.94 \text{ s}^{-1}$ ,  $f(\alpha) = -\ln(1-\alpha)^{1/4}$ , respectively. The kinetic equation of the decomposition process can be expressed as

$$d\alpha/dT = (2.004 \times 10^{11}/\beta) \exp(-1.33378 \times 10^4/T)(1-\alpha)[- \ln(1-\alpha)]^{3/4}$$

To better understand the desorption properties of hydrogen in alane, thermodynamically stable  $\alpha\text{-AlH}_3$  was synthesized [349]. The dependence of phase formation on synthesis pathways and the effect on rates of hydrogen evolution were investigated, and the results were compared with those for  $\gamma\text{-AlH}_3$ . For desorption, all hydrogen atoms of alane evolved under an isothermal condition at 411 K (138 °C) in less than 1 h, and the sample completely transformed to pure aluminum. The results showed that the total amount of desorbed hydrogen from  $\alpha\text{-AlH}_3$  exceeded 9.05 mass-%.

The presence of elemental Al contamination had no impact on the friction sensitivity or impact sensitivity of pure  $\alpha\text{-AlH}_3$  [442]. However, the presence of Al increased the decomposition rate of  $\alpha\text{-AlH}_3$ . In the DSC, the onset temperature of  $\text{Al}/\alpha\text{-AlH}_3$  was lower than that of pure  $\alpha\text{-AlH}_3$ . The dehydrogenation endotherm of  $\alpha\text{-AlH}_3$  had a maximum at 449 K (176 °C).

#### 10.2.4.2 Long-Term Storage Stability of Aluminum Hydride

The storage stability of various samples of aluminum hydride including unstabilized macrocrystalline, magnesium-doped and magnesium-doped, diphenylacetylene (DPA)-treated  $\alpha\text{-AlH}_3$  was monitored under a surveillance program [443]. These samples were tested by themselves at 258, 298, and 313 K (–15, 25, and 40 °C), and in

propellant at 298, 313, and 333 K (25, 40, and 60 °C). Results of surveillance of neat aluminum hydride continue to indicate greater improvement in 298 K (25 °C) stability than was achieved with these samples at 333 K (60 °C). Two samples which previously had suffered 1% decomposition in 18.8 and 25.5 days at 333 K (60 °C) had decomposed by only 0.05 and 0.019%, respectively, after 1 year at 298 K (25 °C). Results of surveillance of aluminum hydride propellant showed decreasing gas generation rates with time. At 298 K (25 °C), a double base propellant containing unstabilized microcrystalline hydride decomposed approximately 0.28 and 0.09% during the first and second year, respectively, and samples containing stabilized aluminum hydride, decomposed only approximately 0.10% during the first year. Small amounts of water in the environment which the aluminum hydride was subjected to have been found to prevent the typical autocatalytic shaped decomposition curve. Instead, an initial gassing period is observed followed by excellent stability. Treatments utilizing small amounts of controlled hydrolysis to improve stability were then recommended. One sample of magnesium-doped aluminum hydride had decomposed only 0.055% after 2 years [444]. Many samples which demonstrated much better 333 K (60 °C) stability were being studied. Correlating aluminum hydride decomposition data using the Avrami–Erofeev equation gave an average activation energy of 96 kJ/mol (23 kcal/mol). High stability magnesium-doped samples have shown even higher activation energies. The equations used for correlating the decomposition data can also be used for predicting the 298 K (25 °C) storage stability from the decomposition data at a higher temperature. The weakest part of this correlation is in the assumption of a particular activation energy. An *n*-butylamine treated sample studied in the neat surveillance program was expected to require 1–3 years to decompose 0.03% based on 2 possible activation energy values.

Once aluminum hydride is embedded in solid propellants, its shelf life may be limited by interactions with other propellant ingredients. For *n*-butylamine passivated Mg-doped aluminum hydride decomposing at the rate of approximately 0.04% per year at 295 K (22 °C), a shelf life of a 1-m (40-in.) web was predicted to be less than 6 months. In the absence of any scavenging or *in situ* stabilizing processes, therefore, at least a fivefold stability/compatibility improvement would be required, i.e., <0.008% decomposition per year, to achieve the desired propellant shelf life [445–447].

#### 10.2.4.3 Reactions of Aluminum Hydride

AlH<sub>3</sub> showed good compatibility with HAP and AP after 70 days at 313 K (40 °C) [318]. The difluoroamino-compound poly-[1,2-bis(difluoroamino)-2,3-propylene oxide] (P-BEP) binder prepolymer was also reasonably compatible with AlH<sub>3</sub> at 313 K (40 °C), but all three NF plasticizers promoted the decomposition of AlH<sub>3</sub> at 353 K (80 °C). No increase in the amount of hydrogen evolved was observed at 333 K (60 °C) and lower, over the time interval studied. Acrylate binder prepolymers posed no serious compatibility problems with AlH<sub>3</sub> and may in fact improve its thermal stability.

Neither HAP or AP appeared to promote the evolution of gaseous decomposition products at 298, 313 or 333 K (25, 40, or 60 °C) for time periods up to 70 days. After 70 days at 353 K (80 °C), the amount of hydrogen evolved from the AP/AlH<sub>3</sub> mixture was the same, within the limits of reproducibility, as that expected from pure AlH<sub>3</sub>. For the HAP mixture, at the same time interval and temperature, the hydrogen evolution was three to four times greater than would be expected from neat hydride.

### Reactions of Aluminum Hydride with Lewis Bases

Adducts of aluminum hydride with Lewis bases are thermally more stable than aluminum hydride itself and can be used as hypergolic fuels. The preferred Lewis base would be ammonia or trimethylamine.

Reaction of aluminum hydride with an excess of trimethylamine gives a white, solid residue of AlH<sub>3</sub>•2N(CH<sub>3</sub>)<sub>3</sub> which sublimes undecomposed in vacuum at 30–40 °C and melts at 368 K (95 °C) [413]. The adduct is a monomer readily soluble in ether, benzene or THF. If one used only a 1:1 molar ratio of AlH<sub>3</sub> and NMe<sub>3</sub>, a more reactive hydride is formed that reacts with air.

The molecular structure of trimethylamine alane, H<sub>3</sub>AlN(CH<sub>3</sub>)<sub>3</sub> was determined by gas phase electron diffraction [448]. The Al–N bond distance in this complex is significantly shorter than the Al–N bond distance in (H<sub>3</sub>C)<sub>3</sub>AlN(CH<sub>3</sub>)<sub>3</sub> and significantly longer than the Al–N bond distances in (H<sub>4</sub>B)<sub>3</sub>AlN(CH<sub>3</sub>)<sub>3</sub> and Cl<sub>3</sub>AlN(CH<sub>3</sub>)<sub>3</sub>.

Tertiary amine-aluminum hydride complexes have gained interest due to their application as chemical reducing agents and in aluminum thin-film deposition. Various alane amine complexes have been made and studied previously, but these compounds were not formed directly using pressurized hydrogen. The direct reaction of catalyzed aluminum, a tertiary amine, and hydrogen in a common solvent proceeded to form an alane amine adduct at moderate pressures and temperatures [449]. A complex of aluminum hydride was formed with dimethylethylamine by this technique. A vibrational analysis of the product of these reactions by Raman and IR clarified the molecular and vibrational structure of alane amine complexes formed by direct hydrogenation. A new method for the formation of alane triethylamine used the direct hydrogenation of dimethylethylamine and catalyzed aluminum followed by transamination with triethylamine. This may lead to a new low-energy method to regenerate AlH<sub>3</sub> from catalyzed recycled aluminum and hydrogen gas and thus close the hydrogen storage cycle.

AlH<sub>3</sub>-amine and Al(CH<sub>3</sub>)<sub>3</sub>-amine adducts were investigated as potential additives for rocket propellant formulations [450]. The investigation included the calculation of property predictions for a variety of known and notional adducts. Property predictions were based on results from quantum chemistry calculational methods. Gas-phase property predictions included Al–N bond dissociation energies (BDEs) and enthalpies of formation at 298 K [ $\Delta H_f(G)(298)$ ]. Condensed-phase property predictions included enthalpies of sublimation [ $\Delta H_s(298)$ ], enthalpies of formation at 298 K [ $\Delta H_f(cond)(298)$ ], and densities ( $\rho$ ). Values derived from measured data or

higher level computational methods were obtained for these properties from open literature sources. These values were employed both to develop and to validate the estimation methods. Assessments of the thermal and/or air stabilities of some adducts were also identified in the course of the literature search, and an attempt was made to correlate the assessments with Al—N BDEs. The  $[\Delta H_f(\text{cond})(298)]$  estimates were employed as input for thermochemical code-based predictions for the specific impulse these adducts could potentially generate when combined with inhibited red fuming nitric acid (IRFNA) as the oxidizer in a rocket engine. Results from the study indicated that several of these adducts warrant further investigation as additives for liquid/gel or solid (hybrid) rocket motor fuels.

The structures adopted by a range of aluminum hydride complexes  $\text{AlH}_3 \bullet n\text{L}$ , ( $n = 1$  or  $2$ ), have been explored in detail to identify the factors that determine the value of  $n$ , and whether a monomeric or dimeric arrangement is preferred for the 1 : 1 complexes [451]. Single-crystal XRD, vibrational, and NMR spectroscopies, and thermal analysis data have been collected. DFT calculations have been performed for  $\text{AlH}_3 \bullet n\text{L}$  species, and  $\text{p}K_a$  values have been collated for a series of amine and phosphine ligands (L). The  $\text{p}K_a$  of the ligand L exerts an important influence on the type of complex formed: as the basicity of L increases, a monomeric structure is favored over a dimeric arrangement. Dimeric amine complexes form if  $\text{p}K_a < 9.76$ , while monomeric complexes are preferred when  $\text{p}K_a > 9.99$ . The steric requirements of L also influence the structural preference: bulky ligands with large cone angles ( $> 163^\circ$ ) tend to favor formation of monomers, while smaller cone angles ( $< 125^\circ$ ) encourage the formation of dimeric or 1 : 2 adducts. Raman spectroscopy and DFT calculations have been particularly helpful in elucidating the stoichiometric preferences and structures of complexes that have been contentious. These included  $\text{AlH}_3 \bullet \text{NMe}_2\text{Et}$ ,  $\text{AlH}_3 \bullet \text{NMe}_3$ , and  $\text{AlH}_3 \bullet n\text{Et}_2\text{O}$ .

One of the thermally most stable  $\text{AlH}_3$  adducts was with tetramethylethylenediamine (2,5-dimethyl-2,5-diazahexane). This compound could be heated to 406 K (133 °C) for long periods without decomposition [452].

### Oxidation of Aluminum Hydride

The oxygen sensitivity of aluminum hydride is dependent on its purity. Generally, all aluminum hydride processes are conducted under an inert gas. The autoxidation of fresh aluminum hydride may lead to accidental ignition in air. Once the particles are passivated, the ignition hazard is reduced. The oxidation of aluminum hydride particles is similar to the oxidation of nanoaluminum, at first a passivation layer forms, and subsequent oxidation is controlled by diffusion of oxygen through the passivation layer. In this second diffusion-controlled conversion step, the diffusion of oxygen occurs from the hole or pore surface of the particle to the bulk metal or the metal to the surface [410]. The oxidation of aluminum hydride is sometimes preceded by or accompanied by loss of hydrogen. A passivation layer forms on aluminum hydride in air, and a similar passivation layer forms in moist air or in water vapor, protecting particles from further reaction.

The combustion of aluminum hydride in air leads to combustion products that contain  $\approx 50\%$  aluminum nitride (by weight) [453]. The formation mechanism of the final combustion products of aluminum hydride is similar to that of ultradisperse metallic aluminum powder burning in air.

#### 10.2.4.4 Ignition of Aluminum Hydride

The ignition of aluminum hydride precedes combustion. Combustion of aluminum hydride will be dealt with in more detail in future sets “Solid Propellants” and “Hybrid Propellants.” Ignition of aluminum hydride may be accidental, such as during the preparation or storage or processing of aluminum hydride, or intentional, such as when it is used as an ingredient in solid rocket propellants.

An experimental investigation on the ignition behavior of  $\alpha\text{-AlH}_3$  used two separate modified T-jump experiments [454]. In each experiment, a small amount of material was placed onto a platinum wire, which was heated rapidly through resistive heating. As a result, both ignition and hydrogen release temperatures were studied for heating rates ranging from  $10^4$  to  $10^5$  K/s. The ignition temperature was studied at ambient pressure in air,  $\text{CO}_2$ , and mixtures of argon with oxygen. Both the hydrogen release and ignition temperature increased as the heating rate increased. Hydrogen release temperatures ranged from approximately 650 to 1200 K. For conditions in which the particles would ignite, the environment did not play a significant role in the ignition temperature, beyond a critical oxygen mol fraction of  $\chi_{\text{O}_2} > 0.05$ . Sample average burning times decreased by a factor of about 3 when the oxygen mol fraction was increased from 0.1 to 0.5. Within experimental uncertainty, there was no difference in the ignition temperature in air or  $\text{CO}_2$ . In both cases the ignition temperature increased as the heating rate increased starting from just below the melting temperature of aluminum (933 K), at the lowest heating rate, to about 1500 K at the highest heating rate.

In order to determine the high-pressure ignition characteristics of  $\alpha$ -aluminum hydride, to quantify the ignition temperature and to observe the ignition process, aluminum hydride particles were heated on a platinum filament at heating rates of approximately  $1 \times 10^5$  K/s in a pressure vessel for pressures ranging up to about 7 MPa [455]. Experiments were conducted in air, argon, and nitrogen as the pressurizing environment. The dehydrogenation of aluminum hydride was not a function of pressure under the conditions tested. In addition, ignition temperatures were found to be approximately linearly related to pressure until pressures exceeded about 0.4 MPa, at which point they remained constant through the remaining highest pressures tested. High-speed imaging of the ignition process showed a dramatic change in the ignition behavior for pressures above 0.4 MPa, corresponding to what is assumed to be a threshold for  $\text{H}_2$ /air autoignition or perhaps even an explosion limit. The combustion behavior of aluminum hydride particles shared many traits with aluminum particles, including a diffusion flame surrounding the particle, spinning, jetting and explosions/fragmentation. Quenched particles showed clear evidence of gas phase com-

bustion with parent particles containing nanofeatures, which had condensed from the gas phase. The results of this study provide additional understanding of the ignition and combustion process of aluminum hydride at extreme conditions, which may be useful in modeling efforts or in the development of solid propellants.

#### 10.2.4.5 Hydrolysis of Aluminum Hydride

Aluminum hydride reacts with water only slowly because the particles are quickly coated with a passivating layer of impermeable  $\text{Al}(\text{OH})_3$  deposits:

This reaction would be a good source of storable hydrogen, but it is not reversible and it would be more difficult to regenerate  $\text{AlH}_3$  from  $\text{Al}(\text{OH})_3$  than from metallic Al.

The exothermic reaction between aluminum hydride and water was studied using a microcalorimeter [456]. The results showed that the standard enthalpy of formation and standard molar heat capacity of  $\text{AlH}_3$  obtained by an extrapolation method were  $-11.49 \text{ kJ/mol}$  and  $45.22 \text{ J mol}^{-1} \text{ K}^{-1}$ , respectively. The values of activation energy  $E$ , pre-exponential factor  $A$  and the reaction order  $n$  for the reaction of  $\text{AlH}_3$  and water over the temperature range from 313 to 328 K were  $69.41 \text{ kJ/mol}$ ,  $108.46 \text{ s}^{-1}$ , and about 1.033, respectively. Aluminum hydride is relatively reactive and may be incompatible with many other propellant ingredients it comes in contact with.

#### 10.2.4.6 Analysis of Aluminum Hydride

Analysis of three different aluminum hydride samples by mass spectrometry with a spark ion source showed that all three samples had contamination from lithium and boron (most likely introduced with lithium borohydride used in the synthesis of  $\text{AlH}_3$ ) and magnesium (a contaminant in the  $\text{AlCl}_3$  used in the synthesis of  $\text{AlH}_3$ ) [457]. The apparatus was able to detect contaminants down to 10 ppm.

### 10.2.5 Other Applications of Aluminum Hydride

#### 10.2.5.1 Gelled Hydrazine with Aluminum Hydride Suspensions

Aluminum hydride has been suspended in gelled hydrazine to be used as a fuel in bipropellant engines or maybe even as a monopropellant by itself. The objective of the study was to find gelling agents that are compatible not only with hydrazine, but also with the  $\text{AlH}_3$  suspended in it [458]. The off-gas generation rate of these formulations was very nearly the same as the off-gas generation rate of an equivalent amount of neat LMH-1 by itself [459]. The presence of water in the hydrazine substantially increased the initial off-gas generation rate of LMH-1/hydrazine formulations, presumably due to reaction of the water with LMH-1. Gelling agents such as lightly cross-linked ammonium polyacrylates have been selected for formulations into LMH-1 heterogeneous systems on the basis of polymeric structure and compatibility. Heterogeneous gels with acrylamide/acrylic acid copolymers have been especially promising due to

their good physical integrity and cohesiveness. Work with ammonium polyacrylate gellants showed that a certain chemical structure is advantageous in obtaining desirable gel characteristics [460]. When pretreated LMH-1 was combined with hydrazine, the amount of gas generated in the initial reaction was reduced and the long-term gas generation rate decelerated in comparison to untreated LMH-1 in hydrazine [461]. The polyacrylamide gelling agent slightly increased the amount of initial gassing of the gelled LMH-1/hydrazine propellant, but the long-term stability equaled the stability of ungelled LMH-1/hydrazine. Fifty pounds of LMH-1/hydrazine heterogeneous propellant was prepared and sent to AFRPL for performance evaluation [462].

#### 10.2.5.2 Aluminum Hydride as a Hydrogen Storage Medium

Aluminum hydride has been evaluated extensively as a hydrogen storage (ideally, a reversible hydrogen storage) material. If alane is to be used as a hydrogen storage medium new and novel methods of regenerating alane from spent aluminum must be found. This application is responsible for the majority of publications on aluminum hydride during the past decades. If aluminum hydride comes to be used as a hydrogen storage medium in automobiles, the expanded availability of aluminum hydride and a better understanding of its properties might benefit its use as a rocket propellant and *vice versa*.

An entire chapter in the book on hydrogen storage [463] is devoted to aluminum hydride and provides a good summary of its properties [464]. With a high gravimetric  $H_2$  storage capacity of 10.1 mass-% H and a hydrogen storage density of  $1.48 \text{ g/cm}^3$ ,  $AlH_3$  makes a good hydrogen storage medium. Aluminum hydride decomposes to its elements above 333 K ( $60^\circ\text{C}$ ) with no side reactions. The properties of  $AlH_3$  were explored in depth, in particular the  $\alpha$ ,  $\alpha'$  and  $\gamma$  polymorphs, of which  $\alpha'$ - $AlH_3$  was reported for the first time, free from traces of other polymorphs [402]. Thermal analysis of  $\alpha$ ,  $\alpha'$  and  $\gamma$ - $AlH_3$  was conducted using DSC, TGA, and pressure composition temperature (PCT) methods, and the results obtained were compared with each other and with literature data. The thermal decomposition of  $AlH_3 \cdot nEt_2O$  was followed by TEM imaging, enabling the pathway and mechanism of decomposition to be identified. Low-level hydrogenation of Al using  $H_2$  gas has been achieved in supercritical fluid reaction media. PCT measurements of hydrogenated samples of Ti-doped Al indicated that 0.33 mass-% H was absorbed in supercritical  $Me_2O$ , while 0.27 mass-% H was absorbed in supercritical  $CO_2$ . The hydrogenation appears to be limited to the surface of the Al particles. See also [465, 466].

## Ternary Metal Hydrides

### 11 Complex Metal Hydrides

While the simple binary metal hydrides of the  $\text{MeH}_n$  type are more likely to be used as rocket propellants, they are not always easy to make. Some of the complex hydrides of the  $\text{Me}^1\text{Me}^2\text{H}_n$  type are more readily available from commercial sources but there is very little experience in using them as rocket propellants. A chapter on complex metal hydrides could fill a book in its own right but we have not attempted to compile a complete review of complex metal hydrides as rocket propellants in this book. Several complex metal hydrides have been tested as ingredients in solid gas generants for generating hydrogen or deuterium gas at short notice, such as for use in a chemical laser for military applications. A mere sampling and incomplete collection of randomly selected references is assembled here in this section, including some review publications on complex hydrides and their potential application as rocket propellants [467, 468]. Many of the complex metal hydrides that were once considered as rocket fuels are now being evaluated as hydrogen storage media, but it is not easy to design a reversible and easily regenerable hydrogen storage cycle based on complex metal hydrides [469]. A book on hydrogen storage contains an entire chapter on complex metal hydrides as hydrogen storage media for fuel cell and other energy storage and conversion applications [470].

Metal borohydrides (also called metal boranates), although they would fit nicely into this current chapter on complex metal hydrides, will be discussed in the chapter “Boranes.” That leaves only the complex magnesium and aluminum hydrides to be discussed in the current chapter.

#### 11.1 Lithium Aluminum Hydride

Aluminum hydride forms complex hydrides (called alanates) with many alkali metal and alkaline earth metal hydrides and also with boranes. The most important example is lithium aluminum hydride, lithium alanate, lithium aluminum tetrahydride, lithium tetrahydridoaluminate,  $\text{LiAlH}_4$ , CAS RN [16853-85-3], which is widely used in the synthesis of other metal hydrides and in the selective reduction of organic unsaturated compounds. Lithium aluminum hydride has been used in the synthesis of aluminum hydride. Lithium aluminum hydride suspensions have been tested for the hypergolization of hydrocarbon fuels but have not found actual flight applications. Lithium aluminum hydride has been considered as a hydrogen storage material because it contains 18.5 mass-% hydrogen but it requires a high decomposition temper-

ature and is too difficult to regenerate [470]. Lithium aluminum hydride can be made by reaction of aluminum chloride with an excess of lithium hydride

Lithium aluminum hydride and other alkali metal aluminum hydrides can be made by direct reaction from the elements in tetrahydrofuran at 423 K (150 °C) under 13.8 MPa (2000 psi) hydrogen pressure [471].

### 11.1.1 Physical Properties of Lithium Aluminum Hydride

Physical properties of lithium aluminum hydride are summarized in Table 18.

**Table 18:** Physical properties of lithium aluminum hydride.

| Property                                | SI units               | Other units                  | References |
|-----------------------------------------|------------------------|------------------------------|------------|
| Molecular mass                          | 37.954 g/mol           | 26.35 mol/kg                 | [10]       |
| Melting point                           | 398 K                  | 125 °C                       | —          |
| Density                                 | 0.92 g/cm <sup>3</sup> | 0.917 g/cm <sup>3</sup>      | —          |
| Standard enthalpy of formation at 298 K | −119 kJ/mol            | −28.4 kcal/mol               | [472]      |
|                                         | −109.6 kJ/mol          | −690 cal/g = −26.19 kcal/mol | [286]      |
|                                         | −117.15 kJ/mol         | −28.0 kcal/mol               | [10]       |
|                                         | −103.2 ± 9.2 kJ/mol    | −24.67 ± 2.21 kcal/mol       | [473]      |
|                                         | −100.8 kJ/mol          | −24.1 kcal/mol               | —          |
|                                         | −117 kJ/mol            | −28 kcal/mol                 | —          |

### 11.1.2 Chemical Properties of Lithium Aluminum Hydride

Lithium aluminum hydride is stable in dry air but reacts with explosive force with water, often with spontaneous ignition. It reacts instantly and hypergolically with hydrogen peroxide, nitric acid, or fluorine.

### 11.1.3 Decomposition of Lithium Aluminum Hydride

The thermal decomposition of  $\text{LiAlH}_4$  as a source of hydrogen has been investigated using isothermal kinetics, DTA, and TGA [474]. The DTA confirmed that the decomposition occurs in four stages. The first stage accounted for only a small percentage of the evolved  $\text{H}_2$  and on occasion exhibited properties of an explosion. Contrary to prior work, the kinetics of the second stage were shown to follow a modified Prout-Tompkins relation. The isothermally determined activation energy of 99.6 kJ/mol (23.8 kcal/mol) for this stage was the same at temperatures both above and below a phase change seen in the DTA; however, the pre-exponential factors

differed in the two regions. The third stage, corresponding to the stoichiometric equation

was found to follow first-order kinetics, with an activation of 196 kJ/mol (46.9 kcal/mol).

The slow pyrolysis of lithium aluminum hydride proceeds by a successive dehydrogenation of the fuel in three stages over a temperature range between 483 and 533 K (210 and 460 °C) [475, 476]. The combustion of lithium aluminum hydride follows a similar multi-stage process in which the pyrolytic dehydrogenation is followed by an afterburning of the metal substrate. Experimental studies were performed to determine the delay times between successive stages for solid mixtures of lithium aluminum hydride with selected oxidizers. Time-resolved spectrographic techniques were used to determine the duration of these stages. Studies were performed using  $\text{Li}_2\text{O}_2$  and  $\text{NH}_4\text{NO}_3$  oxidizers over a particle size range between 75 and 300  $\mu\text{m}$  and O/F mixture ratios of between 0.5 and 3.0. Ignition delay times for the initial reaction were found to vary between 5 and 40 ms for the first stage and 10–120 ms for the second stages.

#### 11.1.4 Applications of Lithium Aluminum Hydride

Lithium aluminum hydride is widely used for the synthesis of other hydrides and for reduction of organic compounds. A solution of lithium aluminum hydride in ether, THF or dioxane and turpentine was patented as a hypergolic fuel in combination with nitric acid [477].

### 11.2 Sodium Aluminum Hydride

Sodium aluminum hydride, sodium alanate,  $\text{NaAlH}_4$ , CAS RN [13770-96-2],  $M = 54.00 \text{ g/mol}$ , is a useful reagent in the preparation of other metal hydrides but is not likely to be used as a rocket fuel. In contrast to sodium borohydride, sodium aluminum hydride is very sensitive to moisture and there are few solvents for it. Sodium aluminum hydride has been considered as a reversible hydrogen storage material but the kinetics of dehydrogenation as well as of rehydrogenation are too slow for any practical application unless it is doped with a suitable catalyst such as  $\text{TiCl}_3$ . There is also a similar sodium aluminum hydride with the formula  $\text{Na}_3\text{AlH}_6$ .

#### 11.2.1 Physical Properties of Sodium Aluminum Hydride

Physical properties of sodium aluminum hydride  $\text{NaAlH}_4$  are listed in Table 19.

**Table 19:** Physical properties of sodium aluminum hydride.

| Property                                | SI units               | Other units        |
|-----------------------------------------|------------------------|--------------------|
| Molecular mass                          | 54.00 g/mol            | 18.52 mol/kg       |
| Melting point                           | 451 K                  | 178 °C             |
| Density at 298 K                        | 1.28 g/cm <sup>3</sup> | —                  |
| Standard enthalpy of formation at 298 K | −115 ± 4 kJ/mol        | −27.5 ± 1 kcal/mol |

### 11.2.2 Decomposition of Sodium Aluminum Hydride

If sodium aluminum hydride were to be used as a reversible hydrogen storage medium for automotive propulsion, the controlled decomposition at the point of end use could be accelerated by titanium catalysts [478].

### 11.3 Magnesium Aluminum Hydride

Magnesium aluminum hydride, magnesium alanate,  $\text{Mg}(\text{AlH}_4)_2$ , CAS RN [17300-62-8],  $M = 86.33 \text{ g/mol}$ , is a lesser known complex hydride. There are no known applications or evaluations of magnesium aluminum hydride as a rocket propellant. Magnesium aluminum hydride has been added to  $\text{AlH}_3$  as a stabilizer. Magnesium aluminum hydride can be prepared by a metathesis reaction of magnesium chloride and sodium alanate followed by purification.

Magnesium alanate has been considered as a material for reversible hydrogen storage. It has a density of  $1.046 \text{ g/cm}^3$ , an enthalpy of formation of  $-152.7 \text{ kJ/mol}$  ( $-36.5 \text{ kcal/mol}$ ) and decomposes at 413 K (130 °C). If it should ever be used on a wider scale for that application, it might become more readily available to be used in rocket propellants. Magnesium alanate was investigated by XRD and TGA and mass spectrometry (MS) of the evolved gas [479]. Thermal analysis showed a decomposition with a release of hydrogen proceeding in two major steps. Measured in vacuum, the peak decomposition temperature of the first step was 436 K (163 °C) and the residue at 473 K (200 °C) consisted of  $\text{MgH}_2$  and Al which continues to release hydrogen and transforms into an  $\text{Al}_3\text{Mg}_2/\text{Al}$  mixture at higher temperatures. In the first decomposition step only 6.6 mass-% of hydrogen was released.

Magnesium aluminum hydride can be made by reactions of lithium and sodium aluminum hydrides with magnesium halides in ether solvents [480, 481]. The ability of these reactions to produce magnesium aluminum hydride depended on the nature of the alkali metal, the halide, the solvent, and the solubility of the alkali metal halide by-product. Contrary to previous reports,  $\text{Mg}(\text{AlH}_4)_2$  could not be prepared by the reaction of  $\text{LiAlH}_4$  and  $\text{MgBr}_2$  in diethyl ether. Magnesium aluminum hydride was prepared in a pure form as the ether solvate by the reactions of  $\text{NaAlH}_4$  and  $\text{MgCl}_2$  in THF or  $\text{NaAlH}_4$  and  $\text{MgBr}_2$  in diethyl ether. Magnesium aluminum hydride is insoluble in diethyl ether

and tetrahydrofuran; thus, it was separated from the NaCl and NaBr by-products by Soxhlet extraction. See also [482, 483].

Magnesium aluminum hydride  $\text{Mg}(\text{AlH}_4)_2$  and calcium aluminum hydride  $\text{CaAlH}_5$  can be synthesized by direct ball-milling of  $\text{AlH}_3$  and  $\text{MgH}_2$  or  $\text{AlH}_3$  and  $\text{CaH}_2$  hydrides [484]. The XRD profiles indicated crystalline compounds.

Magnesium aluminum hydride melts at  $413\text{ K} = 140^\circ\text{C}$  under decomposition and its standard enthalpy of formation is  $-96.6\text{ kJ/mol} = -23.1\text{ kcal/mol}$ . PEPCODED.DAT lists properties of magnesium aluminum hydride as  $\Delta H_f^{298} = -131.8\text{ kJ/mol} = -365\text{ cal/g} = -31.5\text{ kcal/mol}$  and a density of  $\rho = 1.046\text{ g/cm}^3 = 0.0378\text{ lb/in.}^3$  [286]. Other sources list an enthalpy of formation of  $-152.7\text{ kJ/mol}$  ( $-36.5\text{ kcal/mol}$ ).

## 12 Silicon Hydrides (Silanes)

Although silicon and hydrogen are two of the most common elements of the cosmos, their combination, silicon hydrides, are not occurring naturally due to their reactivity with oxygen, immediately combusting to water and silicon dioxide, both combustion products with highly negative enthalpies of formation, thus driving the combustion reaction in the direction of the most stable products.

Silanes have been considered as fuels mostly for air-breathing propulsion, and not so much for rocket propulsion. They can also be used as hypergolic slug igniter fluids with conventional, non-hypergolic fuels.

The main disadvantage of using silanes as rocket propellants is the formation of silicon dioxide slag which is likely to clog the nozzle throat and injector orifices with a glassy coating. In most cases that would mean that the rocket can be started only once; however, at one time, silicone oil has been deliberately added to Agena fuels to provide for a protective coating of silicon dioxide in regeneratively cooled rocket engines. In that case the silicon dioxide film deposition was considered advantageous instead of troublesome, but the Agena engines had to fly only once.

It has been speculated that on distant planets where no carbon can be found in the soil, but somehow water or another source of hydrogen is available, the abundant silicon in minerals could be used to synthesize *in situ* resource utilization (ISRU) silanes as fuels for the trip home.

### 12.1 Preparation of Silicon Hydrides (Silanes)

Silane can be prepared by the reaction of hydrogen chloride with magnesium silicide:

This process gives a mixture of silanes, so-called crude silane (in analogy to crude oil), consisting of about 40%  $\text{SiH}_4$ , 30%  $\text{SiH}_2$ , 15%  $\text{Si}_3\text{H}_8$ , 10%  $\text{Si}_4\text{H}_{10}$ , and 7% higher

silanes [485]. Monosilane can also be prepared from metallurgical grade silicon in a two-step process. First, silicon is treated with hydrogen chloride at about 573 K (300 °C) to produce trichlorosilane,  $\text{HSiCl}_3$ , along with hydrogen gas:

The trichlorosilane is then converted to a mixture of silane and silicon tetrachloride by a disproportionation (redistribution) reaction which requires a Lewis acid catalyst:

Another, more expensive route to silane is the reduction of  $\text{SiCl}_4$  with lithium aluminum hydride  $\text{LiAlH}_4$ .

## 12.2 Physical Properties of Silicon Hydrides (Silanes)

Silane, silicon tetrahydride, tetrahydridosilicon, monosilane,  $\text{SiH}_4$ , CAS RN [7803-62-5] is a structural analog to methane. Its homologue, disilane,  $\text{Si}_2\text{H}_6$ , is a colorless gas. Physical properties of silanes are summarized in Table 20.

**Table 20:** Physical properties of silanes.

| Property                                           | SI units                                 | Other units         | References |
|----------------------------------------------------|------------------------------------------|---------------------|------------|
| <b>Silane <math>\text{SiH}_4</math></b>            |                                          |                     |            |
| Molecular mass                                     | 32.1173 g/mol                            | 31.136 mol/kg       | [10]       |
| Freezing point                                     | 88.1 K                                   | −185 °C = −301 °F   | [312]      |
| Boiling point                                      | 161 K                                    | −111.8 °C = −170 °F |            |
| Liquid density at 188 K                            | 0.68 g/cm <sup>3</sup>                   | —                   |            |
| Viscosity, vapor, at 298 K                         | 115.66 μPs                               | 115.66 μPs          | [486]      |
| Viscosity, liquid, at 100 K                        | —                                        | 0.48 cPs            | [486]      |
| Thermal conductivity, vapor, at 298 K              | 0.0228 W m <sup>−1</sup> K <sup>−1</sup> | —                   | [486]      |

| Freezing point                                     | 141 K                                    | −132.5 °C = −206 °F | [312]      |
| Boiling point                                      | 259 K                                    | −14.5 °C = 7 °F     |            |
| Liquid density at 253 K                            | 0.686 g/cm <sup>3</sup>                  | —                   |            |
| Viscosity, liquid, at 298 K                        | —                                        | 0.148 cPs           | [486]      |
| Viscosity, gas, at 298 K                           | —                                        | 97.6 μPs            | [486]      |

The standard enthalpy of formation of silane gas is +34.31 kJ/mol (+8.2 kcal/mol). With a positive enthalpy of formation, silane can decompose spontaneously into its ele-

ments if heated suddenly, as in a shock tube. The vapor pressure of silane in the temperature range 93.8–161.7 K can be calculated from the Antoine equation [10]

$$\log_{10}(P) = 4.22228 - [703.987/(T + 5.352)]$$

where  $P$  is the vapor pressure in bar and  $T$  is the temperature in kelvin.

Silanes have higher densities than hydrocarbons, due to their much higher molecular masses when compared to their relatives in structure, the hydrocarbons. Also, their liquid temperature range is wider, which is a benefit for non-cryogenic liquid rocket propellants.

The most striking difference of silanes when compared to the alkanes are their heats of formation. While for linear silicon hydrides with the general formula  $\text{Si}_n\text{H}_{2n+2}$ , where  $n$  denotes the chain length, i.e. the number of Si atoms contained in each species, the heats of formation increase by about +40 kJ/mol per  $\text{SiH}_2$  group, the heats of formation of the corresponding alkanes decrease by about 20 kJ/mol per  $\text{CH}_2$  group. Cyclic silanes have even higher enthalpies of formation due to the strain in the rings. Therefore, the decomposition of cyclic silanes in a combustion chamber releases additional energy which may be converted into additional thrust for propulsion.

First-principle computations were performed on the  $n$ -silane series ( $\text{Si}_n\text{H}_{2n+2}$ ,  $n = 1 - 10$ ) [488]. The enthalpy of formation ( $\Delta H_f$ ), Gibbs free energy of formation ( $\Delta G_f$ ), bond length, and bond dissociation energy (BDE) for both the Si–Si and Si–H bonds were predicted from computations. The computed values of  $\Delta H_f$  and  $\Delta G_f$  for lower silanes ( $n \leq 5$ ) were compared to experimental values and used as benchmarks. The increments of the  $\Delta H_f$  and  $\Delta G_f$  values with each increasing  $\text{SiH}_2$  unit for  $n$ -silanes were 40.39 and 58.93 kJ/mol on average, respectively. The length of Si–Si bond increased slightly as the series number increased and then tended to remain constant for higher silanes. The BDE for both the Si–Si and Si–H bonds initially decreased for lower silanes and then approached a constant for higher silanes. The BDE of the Si–Si bonds were smaller than those of Si–H bonds. The higher silanes are more unstable than the lower silanes. The average BDE of Si–Si bond was ca. 302 kJ/mol, which is only half the experimental BDE value of the C–C bond (618 kJ/mol).

## 12.3 Chemical Properties of Silicon Hydrides (Silanes)

### 12.3.1 Silane Reactions

Silane and disilane (a common contaminant in silane) are both pyrophoric in air. The presence of traces of disilane is responsible for the spontaneous flammability of silane produced by acid hydrolysis of magnesium silicide. Even a highly diluted 1% mixture of silane in nitrogen easily ignites when exposed to air. Silane has been used in supersonic combustion ramjets to initiate combustion in the compressed air stream. Silanes have been proposed as combustion enhancer additives to hydrocarbons. Lower molec-

ular mass silanes are soluble in liquid hydrocarbons and can enhance their combustion [485, 489].

### 12.3.2 Decomposition of Silane

The decomposition of silanes to elemental silicon is of practical interest in the production of semiconductor and photovoltaic cell devices by chemical vapor deposition (CVD). The decomposition of silane may precede its combustion. Because silane has a positive enthalpy of formation, it can decompose when heated suddenly. Premature decomposition of silane during storage would prevent its use as an ignition material.

A detailed analytical and kinetic study of the thermal decomposition of monosilane in the temperature range 648–703 K (375–430 °C) and the initial pressure range 4.7–30.6 kPa (35–230 mm Hg) found that the gaseous products in the very early stages of the reaction are hydrogen, disilane, and trisilane [490]. Later in the reaction a solid silicon hydride was formed, its composition varying as the reaction progressed. The reaction is accelerated by the addition of certain foreign gases but is unaffected by packing of the reaction vessel. A tentative mechanism involving the intermediate species silylene,  $\text{SiH}_2$ , was proposed. Similar observations were made when starting with disilane instead of monosilane.

The homogeneous gas-phase decomposition kinetics of silane has been investigated using the single-pulse shock tube comparative rate technique ( $T = 1035 - 1184$  K,  $P_{\text{total}} \approx 533$  kPa  $\approx 4000$  mm Hg) [491]. The initial reaction of the decomposition

is a unimolecular process in its pressure fall-off regime with experimental Arrhenius parameters of:

$$\log k_1 = 13.33 \pm 0.28 - 52700 \pm 1400 / 2.303RT \text{ s}^{-1}$$

The decomposition has also been studied at lower temperatures by conventional methods. The results confirmed the total pressure effect, indicating a small but not negligible extent of induced reaction, and showed that the decomposition was first order in silane at constant total pressures. Good agreement with all the data was obtained with a model whose high-pressure parameters were  $\log A_1 = 15.5 \text{ s}^{-1}$ ,  $E_{1(\infty)} = 238 \text{ kJ} = 56.9 \text{ kcal}$ , and  $\Delta E^0_0 = 234 \text{ kJ} = 55.9 \text{ kcal}$ . When examining the mechanism of the decomposition, it was concluded that hydrogen atoms are not involved. It was suggested that silylene in the pure silane pyrolysis ultimately reacts with itself to give hydrogen:

Kinetic data for static system silane pyrolysis at 640–703 K and 8–53 kPa = 60–400 mm Hg and conversions from 3–30% followed first-order kinetics, with silane loss rates equal to half the hydrogen formation rates [492]. At conversions greater

than 40%, rate inhibition attributable to the back reaction of hydrogen with silylene occurs. Overall reaction rates were not surface sensitive, but disilane and trisilane yield maxima under some conditions were dependent on surface:volume ratios. A non-chain mechanism capable of describing quantitatively all stages of the silane pyrolysis was proposed. After the 1.0% initiation phase, the reaction was both homogeneous (gas phase) and heterogeneous (on the walls), and reaction intermediates were silylenes and disilenes. Free radicals were not involved at any stage of the reaction. The dominant sink reaction for silylene intermediates is 1,2-H<sub>2</sub> elimination from disilane (followed by Si<sub>2</sub>H<sub>4</sub> polymerization and wall deposition).

The thermal decomposition of silane highly diluted in argon was observed behind reflected shock waves over the temperature range from 1060 to 1730 K and pressures between 61 and 506 kPa (0.6 and 5.0 atm) [493]. Silane and silylene time histories were monitored using the infrared emission of SiH<sub>4</sub> near 4.7 μm and laser absorption of a SiH<sub>2</sub> transition near 579 nm. Reaction rate coefficients for the first-order and second-order forms of the decomposition reaction

were determined from the species measurements for M = Ar. The bimolecular rate constant over the pressure range considered was determined to be

$$k_{1a} = 7.2 \times 10^{15} \exp(-E/RT)$$

where  $k_{1a}$  is the rate constant in cm<sup>3</sup> mol<sup>-1</sup> s<sup>-1</sup> and  $E$  is the activation energy  $E = 188.7 \pm 5.0$  kJ/mol =  $45.1 \pm 1.2$  kcal/mol. This second-order rate coefficient described the silane decomposition reaction over the entire range of temperatures and pressures and showed good agreement with the results of previous studies at similar temperatures as well as those at lower pressures and at temperatures above and below the values referenced above. The implication of the second-order reaction rate is that even at total mixture pressures as high as 5 atm, the silane decomposition is still in the low-pressure limit. A pressure-dependent rate equation is therefore not needed for SiH<sub>4</sub> decomposition over a wide range of conditions of practical interest when the reaction is simply expressed in the bimolecular form.

#### 12.4 Toxicity of Silane

Unlike methane, silane is very toxic. The lethal concentration in air for rats (LC50) is 0.96% (9600 ppm) over a 4-h exposure. The NIOSH has set a recommended maximum allowable exposure limit of 5 ppm (7 mg/m<sup>3</sup>) over an 8-h time-weighted average.

## 12.5 Handling of Silane

The handling of silanes requires safety precautions to prevent accidental leakage and ignition [494–496].

## 12.6 Combustion of Silicon Hydrides (Silanes)

The ignition and combustion of silane is mostly of interest for air-breathing engines, but also for the hypergolic start of non-hypergolic fuels in rocket engines. The addition of silanes to hydrocarbon fuels will enhance their ignition, increase heat of combustion and accelerate the burning velocities. While experiments with silanes in current combustion engines will be discussed in future volumes on bipropellant combinations, the current sections summarize only the studies of more academic interest, where many of the experiments could be conducted in glass apparatus.

Self-ignition and flame propagation properties of silane combustion have been studied through computer simulations using a database of kinetic and thermodynamic information that was consistent with current understanding of the elementary processes, including the mechanism for chain branching through the  $\text{SiH}_3$  radical, rate constants for the reactions of  $\text{HO}_2$  with silane and its breakdown products, and the reaction of  $\text{SiO}$  with oxygen [497]. Over the entire temperature range, the simulations showed two distinct mechanisms. At low temperatures, the kinetics of  $\text{SiH}_3$  is controlling, whereas at high temperatures,  $\text{SiH}_2$  chemistry is of key importance. The upper explosion limit and ignition at room temperature and 1 bar can be described by the same set of reactions. For very lean flames, the maximum reaction rate occurs at the lower temperature region of the flame zone.

### 12.6.1 Limits of Flammability of Silicon Hydrides

There have been several accidents caused by silane leaks in the semiconductor and photovoltaic cell processing industry [498]. Accident investigations have concentrated on the limits of flammability in air and on the conditions leading to autoignition and explosions when silane leaks out into air. Research was carried out to develop improved protection guidelines for silane handling systems through enhanced understanding of the behavior of releases of this pyrophoric gas. The approach involved addressing various aspects of the problem: The autoignition behavior of silane; the reactivity characteristics of quiescent silane/air mixtures; and the rates of reaction of silane leaked into enclosures with and without explosion venting, in the presence of ventilation air flow.

When measuring the explosivity of monosilane-air mixtures, the limiting oxygen concentration at which monosilane will not self-ignite in a nitrogen-oxygen atmosphere was 0.7–3%, depending on the humidity of the medium [499]. Monosilane

autoignition was observed at very low temperatures. Reducing the temperature of the nitrogen-oxygen medium only slightly raised the oxygen autoignition limit. Methyl iodide effectively inhibited the ignition of monosilane in air for near-stoichiometric mixtures.

Contrary to previous information, the ventilation flow has no measurable effect on the prompt ignition of a silane release. From experiments in a 5.1-L (311-in.<sup>3</sup>) sphere it was found that silane/air mixtures of concentrations between 1.4 and 4.1% (by volume) are explosive but stable [500]. In this case, piloted ignition tests yielded laminar burning velocities up to 5 m/s (1000 ft/min). Mixtures between 4.5 and 38% (the maximum reached in the tests) were found to be metastable, and would undergo spontaneous ignition after a delay ranging from 15 to 120 s, with the shorter values corresponding to higher silane concentrations. Experiments were also performed in a 0.645 m<sup>3</sup> (22.8 ft<sup>3</sup>) vessel both with and without explosion venting, to measure the rates of energy release associated with impulsively started silane leaking from 1/8 and 1/4-in. (3.2 and 6.4 mm) lines. A method for the prediction of the venting requirements of partial-volume deflagrations was developed to quantify the pressure rise from ignition of silane leaks in enclosures.

### 12.6.2 Autoignition of Silane in Air

While silane is a pyrophoric gas with a wide range of flammability, releases into the air may not always ignite immediately or sometimes not at all. The spontaneous ignition of pre-mixed silane-oxygen-nitrogen mixtures has been investigated under a variety of conditions. Silane when released at high velocities may not immediately ignite. The smaller the diameter of the release tube is, the lower is the pressure at which no ignition would occur. It was found that the autoignition temperatures were lower than room temperature even if the oxygen concentration was extremely low [501]. The spontaneous ignition of silane takes place in extremely oxygen-lean mixtures, like those which are instantaneously produced when silane or silane mixtures are vented into the air, as in an accidental leak.

Spontaneous ignition limits of silane have been investigated at relatively low concentrations [502]. For silane, the spontaneous ignition occurred if the mixture concentrations were such that the silane/oxygen ratio was higher than a certain threshold limit value. The mixture was not stable if the ratio was higher than a certain value. It was concluded that the spontaneous ignition of silane occurs as a result of a competition of both chain branching and chain breaking reactions, in a way that is qualitatively similar to that in hydrogen oxidation.

A mechanism of low temperature silane combustion has been proposed based on the assumption that a trace amount of water facilitates spontaneous ignition of silane in air at room temperature [503]. This assumption has been made based on the fact that the combustion product of silane positively influences the occurrence of spontaneous ignition. Energetic calculation of the reaction pathway for low temperature

silane combustion also supported this assumption. A numerical model was developed which could interpret the spontaneous ignition limit at room temperature, the ignition delay times and the second explosion limit of silane mixtures.

The concentration of silane in fuel required to achieve ignition was investigated using a practical, non-premixed, oxygen-methane, swirled-stabilized burner in a laboratory [504]. The effects of fuel and oxidizer injection timing, flow rates, injector configuration, silane gas temperature (273–325 K), and combustion system geometry were investigated. In each case the minimum silane concentration in methane necessary for prompt, repeatable ignition was recorded. The role of methane as a diluent in low-temperature silane autoignition for a methane-oxygen combustion system was examined to serve in the design of a flight engine.

A chemical kinetic reaction mechanism for the oxidation of silane/hydrogen mixtures was based on shock-tube ignition delay time data [505]. Good agreement between experimental results and the results predicted by the mechanism was obtained by adjusting the rate coefficient for the reaction of the silyl radical

The reaction mechanism was used to theoretically investigate the ignition characteristics of silane/hydrogen mixtures in air. The results revealed that over the entire range of temperature examined (800–1200 K), substantial reduction in ignition delay times can be obtained when silane is added to hydrogen. Silane is a pyrophoric gas commonly used in semiconductor and photovoltaic cell manufacturing and has also been considered as a fuel additive to improve flame stabilization in scramjet engines.

Calculations have been made to demonstrate the use of silane/methane liquid mixtures as an ignition promoter and flame stabilizer in hydrogen (or other) fueled scramjet applications [506]. The calculations showed that initially non-flammable mixtures undergo rapid methane evaporation to produce droplets capable of spontaneous inflammation. This technique may be expanded to other spontaneously flammable materials. It was assumed that the liquid silane/methane mixture was sprayed into the combustion chamber upstream of the main fuel injectors. Droplet size, flow velocity, temperature and initial liquid fuel mixture composition were varied.

A chemical kinetic mechanism was proposed for the combustion of oxygen-silane-hydrogen-nitrogen mixtures in the initial temperature range from 800 to 1250 K and pressure range from 51 to 137 kPa (0.5–1.35 atm) [507]. Predicted ignition results agreed with published ignition delay times obtained from shock-tube experiments. Comparisons between the results obtained using the proposed mechanism and that of an alternative mechanism revealed that the former predicts appreciably shorter ignition delay times, but a flame blow-out envelope which was shifted so as to decrease the stable flame region. Over much of the thermodynamic range examined, the mechanism predicted long reaction times. A three-step global mechanism was proposed which closely modeled the ignition phase of air/SiH<sub>4</sub>/H<sub>2</sub> combustion; however, the

initial reaction phase was less well reproduced by the global model, which could not be confirmed without additional experimental data.

The products of oxygen (air) + silane mixture combustion and explosions vary with mixture composition [508]. For O<sub>2</sub>-rich mixtures (> 70% O<sub>2</sub>), the products are H<sub>2</sub>O and SiO<sub>2</sub>. As the mixtures become richer in silane, H<sub>2</sub> replaces H<sub>2</sub>O as a final product. For very SiH<sub>4</sub>-rich mixtures (> 70% SiH<sub>4</sub>), the products are H<sub>2</sub>, SiO<sub>x</sub>, and Si. The fact that silane is totally consumed in silane-rich mixtures (70–90% silane) demonstrates that solid particle formation (SiO<sub>2</sub>, SiO, and Si) occurs very rapidly and that the accompanying heat release is essential to drive the reactions to completion. It is also clear that the explosion of silane-rich mixtures is primarily a thermal explosion of silane by itself, which does not depend on the presence of an oxidizer.

A shock tube was used to measure the ignition delay time of stoichiometric O<sub>2</sub>/H<sub>2</sub> mixtures with and without addition of 25% silane to the hydrogen fuel [509]. The shock-tube conditions were 880–1600 K and 172–517 kPa (1.7–5.1 atm). The ignition augmenting effects of silane were more pronounced at lower temperatures (880–1300 K) than at high temperatures. The slope of the ignition delay time versus reciprocal temperature was different at low temperatures than at high temperatures.

If silane is to be used as an ignition fluid, it is important to know how fast it ignites and how the ignition delay is affected by O/F ratio, diluents, and pressure. Ignition studies were performed behind shock waves in a shock tube using SiH<sub>4</sub>, O<sub>2</sub>/SiH<sub>4</sub>, O<sub>2</sub>/H<sub>2</sub>, O<sub>2</sub>/SiH<sub>4</sub>/H<sub>2</sub>, O<sub>2</sub>/CH<sub>4</sub>, and O<sub>2</sub>/SiH<sub>4</sub>/CH<sub>4</sub> highly diluted in argon [510]. Reflected-shock temperatures ranged from 1050–2250 K at pressures near 101 kPa (1 atm). Reaction progress was monitored by observing the time concentration histories of several species, including OH\*, SiH<sub>4</sub>, SiH<sub>2</sub>, and CH\* using emission and laser absorption techniques. The oxidation and ignition data were reported in the form of species concentration profiles and plots of characteristic delay times as a function of temperature. The species concentration time histories exhibited a dual oxidation behavior for most of the fuel/O<sub>2</sub>/SiH<sub>4</sub> experiments, indicating that silane reacts first, followed by reaction of the fuel with the remaining oxygen. As expected, the presence of silane in the O<sub>2</sub>/fuel mixtures markedly reduced the ignition delay time, usually by a factor of two or more even at molar SiH<sub>4</sub> concentrations as low as 1% of the fuel concentration. The shock-tube kinetic data can be used to validate chemical kinetics models of high temperature silane oxidation for propulsion and materials processing applications.

Several dilute mixtures of varying concentrations and equivalence ratios ( $\Phi = 0.5, 1.0$ ) of O<sub>2</sub>/Ar/C<sub>2</sub>H<sub>4</sub>/SiH<sub>4</sub> were studied between 1115–1900 K and 91–334 kPa (0.9–3.3 atm) [511]. Argon dilution ranged from 96–98% with total concentrations between 0.67 and  $3.2 \times 10^{-5}$  mol/cm<sup>3</sup>. Reaction was monitored using chemiluminescence emission from the hydroxyl radical near 307 nm. For SiH<sub>4</sub> concentrations less than those of ethylene in the mixture (by volume), the ignition delay time was reduced by ~30 to >50%. The addition of SiH<sub>4</sub> had a small effect on ignition activation energy, indicating the chain branching mechanism for C<sub>2</sub>H<sub>4</sub> ignition was speeded up but not altered greatly by the silane at higher temperatures. After

adding an appropriate  $\text{OH}^\bullet$  free radical submechanism, several kinetics mechanisms containing high-temperature ethylene chemistry were compared to the data without  $\text{SiH}_4$ . Most of the mechanisms predicted the ignition activation energy quite well. The basic formation and quenching characteristics of the  $\text{OH}^\bullet$  profiles were reproduced by most mechanisms, but each required some adjustment to match all features.

Silane is a pyrophoric gas which normally ignites upon contact with air; however, a silane release from a pressure source may not always lead to prompt ignition and frequently the ignition occurs only shortly after the release is shut off. In a confined space, significant quantities of unburnt silane can accumulate prior to autoignition, leading to an explosion, potentially causing significant damage. A series of tests was aimed at a better understanding of the precise conditions for pure silane ignition and explosion upon release into air [512, 513]. Tests were performed for releases at controlled and steady flow velocities. With careful control of test conditions, the critical exit flow velocity for prompt ignition of steady silane releases was found for different vent diameters. If the releases were reduced to below the critical exit velocity, prompt ignition of silane release was observed. Above this critical exit velocity, silane can be released indefinitely into air without any ignition. The critical exit velocity was found to vary with the vent diameter. The most reactive ignition kernel occurred in the range when the ratio of volumetric flow rate of entrained air to the silane flow reached  $0.322 \pm 0.076$ , which was equivalent to the most reactive silane concentration of 75.6% in air.

Ignition of pure silane upon release into air always occurred in a well-defined mixture fraction called the most reactive mixture fraction. The critical exit velocity and the most reactive mixture fraction suggest that silane release without prompt ignition is most likely caused by flow strains or by scalar dissipations, which prevent chemical reactions of silane oxidation [514].

The critical velocity for delayed ignition was determined for different silane temperatures and moisture contents in ambient air [515]. The logarithm of the critical exit velocity was found to be inversely proportional to silane temperature. Moisture in air had a strong inhibiting effect on silane autoignition in air. Prompt ignition of silane was favored in a high-temperature and low-humidity environment.

During field experiments on unconfined explosions of silane-air mixtures in a cubic frame covered with a thin vinyl film, ignition from the tube exit located at the center of cubic frame was initiated by shutting off the silane flow [516]. Silane/hydrogen mixtures are used during elemental silicon production and semiconductor processing but constitute an acute ignition and explosion risk if accidentally released into ambient air [517, 518]. Additional information on ignition and combustion of silanes in ramjet and rocket engines will be contained in a future volume on hypergolic bipropellant combinations.

### 12.6.3 Flame Speeds of Silicon Hydride Combustion

Addition of silanes to hydrocarbon fuels may raise the flame speeds sufficiently such that these fuels can be used in pulsed detonation engines or rotating detonation engines. One of the fuels already tested in these engines is ethylene. Adding silane to ethylene enhances its ignition and combustion in compact combustors with limited chamber volumes.

The burning velocities of lean pre-mixed silane-oxygen-nitrogen flames were measured in the silane and oxygen concentration ranges from 1.6 to 2.9% and from 4 to 24%, respectively [519]. The burning velocity of a silane-air flame was ~55 cm/s at a silane concentration of 2%. For lean mixtures, when the oxygen concentration was reduced, dependence of burning velocity on silane concentration decreased but did not significantly affect the flame temperature. For extremely lean flames, the degree of hydrogen production increased with decreasing silane concentration and silane was almost completely consumed. On the other hand, if the silane concentration exceeded the stoichiometric point, the burning velocity increased gradually with increasing silane concentration. In that case, silane as well as oxygen were completely consumed and, at the same time, hydrogen rather than water production became dominant. The burning velocity of silane in 21% O<sub>2</sub>/balanced N<sub>2</sub> increased from zero near the lower limit of flammability (1.5% SiH<sub>4</sub>) to 3 m/s at 4.5% SiH<sub>4</sub>.

Exposure of the reactor walls to the products of the low-pressure silane-oxygen flame at a temperature of 523–773 K (350–500 °C) activates the wall as a catalyst of heterogeneous chain initiation [520]. It was shown that new lattice structures saturated with crystal lattice defects are formed, whose number on the wall increases continuously during condensation of the reaction products, together with adsorption of silicon-containing free radicals.

The combustion mechanism of air/silane flames was studied through a computer simulation employing a detailed chemical kinetic scheme [521]. Two different pathways for the consumption of silane were found: SiH<sub>4</sub> → SiH<sub>3</sub> → SiH<sub>2</sub>O → HSiO, which proceeds in low-temperature regions, and SiH<sub>4</sub> → SiH<sub>2</sub> → HSiO, occurring at high temperatures. This observation supported results previously reported in the literature. It was also found that some reactions occurred over wide ranges of temperature and that the governing step for the whole silane combustion is the reaction of silane with hydroxyl radicals. A least-square fitting to the burning velocities and adiabatic flame temperatures obtained for the four investigated mixtures, with equivalence ratios of  $\Phi = 2.0, 1.43, 1.0$ , and  $0.5$ , indicated that a mixture with equivalence ratio of about 1.2 would have the fastest burning velocity and the highest flame temperature. The simulation of silane-air flat pre-mixed flames using a detailed reaction scheme with 45 reactions and the analyses of the obtained results led to the following conclusions: **(1)** in the flames with equivalence ratio around 1.0 the combustion reactions take place very intensely, and consequently are confined within thin areas of the flame about 0.05 mm thick. The burning velocity of the stoichiometric flame was 2.2 m/s, which is a little slower than that of the hydrogen flame. **(2)** Two mechanisms were provided for

the reaction from  $\text{SiH}_4$  to  $\text{HSiO}$ : one proceeds along  $\text{SiH}_2\text{O} + \text{HSiO}$  and the other along  $\text{SiH}_4 + \text{SiH}_2 + \text{HSiO}$ . These pathways are activated in different temperature ranges. The former starts even at low temperatures because it progresses as chain reactions having hydroxyl radicals as chain carriers, which are produced in a large amount even at low temperatures. The latter is activated at high temperatures because the initiation reaction of this route has a large activation temperature. The second mechanism is also accelerated under rich conditions since it starts with dissociation of silane.

A detailed chemical reaction scheme and a full set of governing equations for fluid dynamics were used to demonstrate the chemical and physical phenomena involved in an air/silane counterflow diffusion flame, where the fuel and air issue from a lower and an upper nozzle [522]. It was found that a stagnation surface, where the axial velocities decrease to zero, is kept in a position slightly shifted to the upper side, dividing the system into two zones: the upper air side and the lower fuel side. After leaving the nozzle silane begins to dissociate into  $\text{SiH}_2$  and  $\text{H}_2$  when it reaches the region of rising temperature. Oxygen penetrates into the fuel side by diffusion and reacts with  $\text{H}_2$  forming OH radicals and H atoms. The  $\text{SiH}_2$  intermediate is further dehydrogenated to  $\text{SiO}$  via  $\text{HSiO}$ . When compared to pre-mixed flames, the diffusion flames have large local equivalence ratios, so that the combustion reactions in the latter flames proceed through a different mechanism.

## 12.7 Applications of Silicon Hydrides

It is unlikely that silanes would ever be used as the main fuels in bipropellant rocket engines [523]. They could be used as ignition aid for a hypergolic slug start prior to switching to the main fuel which is only non-hypergolic without addition of silane [524]. Silane has been used in supersonic combustion ramjets to initiate combustion in the compressed air stream. Monosilane was successfully used in the hypersonic NASA X-43A scramjet flights as an ignition aid [525, 526]. Silanes have been proposed as combustion enhancer additives to hydrocarbons [489].

# Methylhydrazine

## Methylhydrazine

*Encyclopedia of Liquid Fuels* contains four chapters dealing with hydrazines: Chapter “Hydrazine” dealing with the parent compound, the inorganic compound hydrazine, chapter “Alkylhydrazines” dealing with alkylhydrazines other than methylhydrazine or dimethylhydrazine, chapter “Dimethylhydrazines,” and finally, chapter “Methylhydrazine,” the chapter at hand.

Methylhydrazine, also known as monomethylhydrazine, hydrazinomethane,  $\text{H}_2\text{NNHCH}_3$ ,  $\text{C}_1\text{N}_2\text{H}_6$ , MMH, Chemical Abstracts Service Registry Number CAS RN [60-34-4], is the simplest alkylhydrazine and widely used as a hypergolic rocket fuel. Methylhydrazine is usually erroneously called *monomethylhydrazine* (often abbreviated as MMH). As the corresponding amine is called methylamine and not monomethylamine, and as there are no structural isomers depending on which nitrogen atom the methyl group is attached to (as long as they are both  $^{14}\text{N}$ ), the prefix *mono* is considered an unnecessary waste of print space.

## 1 Production of MMH

At a cursory glance, one might assume that the simplest way of preparing MMH would be to methylate hydrazine (Section 1.2.3). This is not the case. Even if the direct methylation of anhydrous hydrazine did lead to the desired product, the MMH would be much more expensive than the anhydrous hydrazine used as a starting compound if it had to be made this way. Methylhydrazine can be produced more economically using a modified Raschig process by substituting methylamine in the second step of the reaction [1] (see Section 1.1). The reaction can be carried out in aqueous solution or in excess amine [2].

It appears that so far, most of the MMH used as rocket propellant has been produced in the US, and other countries such as Russia (former USSR), France, China, or India have used more unsymmetrical dimethylhydrazine (UDMH) than MMH, but these countries have also maintained the ability to make smaller quantities of MMH.

In an effort to become independent of MMH imports, France developed its autonomous MMH manufacturing capability, and in doing so, evaluated several MMH and UDMH manufacturing processes. The most promising route chosen for the national production of MMH in France was a modified Raschig process. Supporting studies were documented in a series of doctoral theses and reports published by the University of Lyon [3, 4]. An explosion at the neighboring AZF chemical plant in Toulouse in September 2001 interrupted MMH and UDMH production at SNPE for 3 years.

### 1.1 Preparation of Methylhydrazine Using a Modified Raschig Process

Methylhydrazine can be prepared by a variation of the basic Raschig synthesis in which chloramine is first formed in the conventional manner, but the ammonia in the second-stage reaction is replaced by methylamine:

A similar method using dimethylamine instead of methylamine can be used for the production of UDMH. Substantial effort has gone into optimizing the reaction conditions to maximize the MMH yield in a small (30 g MMH/h) pilot plant, in particular to define the optimal pH, chloramine:methylamine mixture ratio, operating temperature, and dwell time. Kinetic equations were derived for all major process steps. The MMH was isolated from the primary reaction product mixture using a four-step process: **(1)** stripping of the unreacted volatiles ( $\text{NH}_3$ ,  $\text{CH}_3\text{NH}_2$ ), **(2)** distillation of an azeotropic mixture, **(3)** breaking the azeotrope by the addition of NaOH, and **(4)** distillation of the MMH-rich phase. The phase diagrams of MMH in a mixture with water, NaCl, and NaOH have been extensively investigated as they determine the amount of sodium hydroxide needed and the mass of waste generated that needs to be disposed of at a substantial cost. The studies included ternary MMH/water/NaOH [5] as well as quaternary MMH/water/NaOH/NaCl systems [6]. Isotherms at 288, 298, and 313 K were measured and the liquid–liquid miscibility gap was pretty well bracketed from both sides. It was shown that the concentration of MMH in the lighter phase increased with decreasing temperature.

In all modifications of the Raschig process for making MMH, UDMH, or hydrazine, it is important to have an efficient way of making chloramine without losing too much active chlorine during the first step. The chloramine yield depends on the pH of the ammonia or ammonium chloride solution reacting with sodium hypochlorite and needs to be optimized [7].

Instead of generating the chloramine by reaction of ammonia and hypochlorite, chloramine can be synthesized electrochemically by electrolysis of a solution of ammonia and ammonium chloride, with subsequent extraction of the chloramine [8, 9]. The electrolysis conditions were optimized using a three-electrode cell. The electrochemical yield was close to 70%. A similar study using ammonium bromide to generate bromamine gave  $\text{NH}_2\text{Br}$  with 100% yield. A suitable immiscible solvent for extraction of chloramine is methyl-*tert*-butyl ether, which until recently was widely used as a gasoline additive. The extracted chloramine can be reacted with methylamine at 288 K instead of 343 K (as was common for the aqueous-phase reaction), leading to fewer by-products and MMH yields up to 78% [10, 11]. In order to find a way of preparing MMH using Raschig synthesis in a biphasic medium with methyl-*tert*-butyl ether

(MTBE) as the organic phase, the solid/liquid/vapor quaternary system  $\text{CH}_3\text{NH}_2/\text{H}_2\text{O}/(\text{CH}_3)_3\text{COCH}_3/\text{NaOH}$  has been investigated at 288 K [12]. By the addition of NaOH to a mixture of  $\text{CH}_3\text{NH}_2/\text{H}_2\text{O}/(\text{CH}_3)_3\text{COCH}_3$  three liquid phases were observed in a first step, and an isothermal–isobaric four-phase invariant equilibrium may be obtained (three liquids and one vapor). This procedure can be carried out as a continuous process, as was demonstrated using a pilot-scale unit in the laboratory. The by-products resulting from degradation remained in the organic phase.

The production of MMH or UDMH by the modified Raschig process may form small amounts of hydrazine as a by-product. Although the presence of a little hydrazine does not interfere when MMH or UDMH is used as a rocket fuel, it may lead to undesirable side reactions when MMH or UDMH is intended to be used for the synthesis of pharmaceutical or agrochemical products. Traces of hydrazine can be selectively removed from a MMH or UDMH solution by heating it in contact with catalysts that do not destroy any alkylhydrazines (nickel supported on silica/alumina, nickel–nickel oxide mixture supported on silica/alumina, or rhodium supported on carbon at a temperature between 333 and 393 K = 60 and 120 °C) [13].

### 1.1.1 Reaction Kinetics and Mechanisms

The mechanism of the reaction between chloramine and methylamine is almost identical to that of the Raschig synthesis. The  $\text{S}_\text{N}2$  mechanism was studied [14], and it supported conclusions drawn earlier about the nucleophilic type of attack on the chloramine. Similar reactions occur with secondary amines in place of primary amines, leading to unsymmetrical dialkylhydrazines. The rate of MMH formation can be expressed by the equation:

$$V = \frac{d[\text{CH}_3\text{NHNH}_2]}{dt} = k_1[\text{NH}_2\text{Cl}]^\alpha[\text{CH}_3\text{NH}_2]^\beta - ck_2[\text{NH}_2\text{Cl}]^\gamma[\text{CH}_3\text{NHNH}_2]^\delta$$

where  $k_1$  is the rate constant of the MMH-forming reaction and  $k_2$  is the rate constant of an undesirable side reaction in which MMH is destroyed. The exponents  $\alpha$ ,  $\beta$ ,  $\gamma$ , and  $\delta$  determine the order with which reactants enter into the reaction. These orders and the rate constants of unit reactions can be determined by working with a large excess of one of the reactants, in this case typically methylamine, and monitoring the rate of disappearance of the other reactant (chloramine) and the rate of appearance of the desired product (MMH). Measurements have shown that the exponents  $\alpha$  and  $\beta$  are equal to 1 [15, 16]. The MMH formation reaction is thus first order in both reactants. The first step of the MMH-forming reaction is independent of pH, but the second is accelerated by increasing the pH. For an initial methylamine: chloramine ratio of 10, the optimal MMH yield is achieved at a pH of 13.5. Increasing methyl substitution (the methyl group is an electron donor) on the ammonia molecule makes the molecule more reactive in an  $\text{S}_\text{N}2$ -type mechanism, as summarized in Table 1.

**Table 1:** Rate constants of chloramine reactions with amines.

| Number of methyl groups | Amine                              | Hydrazine formed                                 | Constant $\lambda$ , L mol <sup>-1</sup> s <sup>-1</sup> |
|-------------------------|------------------------------------|--------------------------------------------------|----------------------------------------------------------|
| 0                       | NH <sub>3</sub>                    | N <sub>2</sub> H <sub>4</sub>                    | $1.04 \times 10^{-4}$                                    |
| 1                       | CH <sub>3</sub> NH <sub>2</sub>    | CH <sub>3</sub> NHNH <sub>2</sub>                | $48.7 \times 10^{-4}$                                    |
| 2                       | (CH <sub>3</sub> ) <sub>2</sub> NH | (CH <sub>3</sub> ) <sub>2</sub> NNH <sub>2</sub> | $899.5 \times 10^{-4}$                                   |

Data source: [15]

The MMH yield is limited by several unwanted reactions, in particular, the chlorine transfer from chloramine to methylamine [17–19]:

and the oxidation of MMH by chloramine [20]. Chlorine transfer is maximum at a pH of 10 and decreases to a constant value above pH 12.8. MMH oxidation by chloramine is the result of two competitive reactions, the first one being pH independent, and the second one being accelerated by decreasing pH. The optimal pH for MMH formation would be above the range where chlorine transfer and MMH oxidation can take place. MMH oxidation by chloramine leads to a mixture of unwanted by-products, including methanol, methyl chloride, and formaldehyde methylhydrazone  $\text{CH}_3\text{NHN}=\text{CH}_2$ .

Chloramine for the production of MMH by the Raschig process can be synthesized under stoichiometric conditions, which leads to a more economical process because it avoids the additional steps of extraction due to the presence of excess reagents [21]. However, chloramine is not very stable and, therefore, it was important to study its stability. Differential scanning calorimetry (DSC) analyses of stoichiometric chloramine solutions revealed a risk of decomposition above 309 K (36 °C). Limiting the temperature rise requires efficient cooling in the synthesis reactor or synthesis at a low temperature, in order to avoid any sudden decomposition of the synthesis solution.

### 1.1.2 Industrial MMH Plant Designs and Flowcharts

The process flow chart of an MMH production facility designed by Olin Mathieson (then Olin Chemicals, later Arch Chemicals, Lonza, now Arxada) is illustrated in Figure 1.

In the Olin process, liquid chlorine and precooled dilute (12%) caustic soda are mixed to form fresh sodium hypochlorite solution. An excess of aqua ammonia (5%) is reacted with the hypochlorite solution to form a solution of chloramine. Up to this step everything is similar to the production of hydrazine itself. The major difference is in the next step, where chloramine is reacted with anhydrous methylamine in a specially designed reactor to form MMH. The effluent from the reactor is a very dilute aqueous solution of MMH. Excess unreacted methylamine and ammonia are present as impurities, sodium chloride as a reaction by-product. The purification and concentration

**Figure 1:** Process flow chart of methylhydrazine production. (Republished from [22], with permission from Wiley Interscience New York.)

of the product requires five process steps. Ammonia and methylamine are recovered in distillation columns and recycled. The nitrogen, a product of undesirable side reactions that limit the MMH yield, is recovered and used to blanket the concentration columns where explosive vapor concentrations could exist. The bottom of the ammonia-methylamine recovery columns contains only water along with sodium chloride and MMH. The sodium chloride is crystallized in an evaporator and removed by centrifuging. The dilute MMH solution is then concentrated in a three-step train of distillation columns. The first concentration column yields as overheads distilled water that is used for process dilution. The partially concentrated MMH solution from the bottom of the first column is fed to the second column, called the azeotrope column, which yields an MMH/water azeotrope (35% MMH). In the finishing columns, the azeotrope is broken with a very concentrated solution of sodium hydroxide. The ability of sodium hydroxide to lower the vapor pressure of water selectively allows the production of at least 98% pure MMH.

Whereas at least one mol of NaOH per mol of water is needed to break the hydrazine/water azeotrope (see Section 2.3), very little NaOH is required to break the MMH/water azeotrope. Azomethane (a potentially hazardous contaminant that has been the cause of an explosion [23]) and unreacted methylamine form a constant boiling azeotropic mixture that can be readily removed by fractional distillation of the first overhead stream of the reaction product of chloramine and excess methylamine in aqueous solution [24]. The methylamine is recycled to the process. The MMH is obtained with the water phase that is the bottom of the first column. The azeotrope contains approximately 90 mol-% methylamine and boils at 275–280 K. In order to prevent the accumulation of azomethane (AM), which is explosive, steam is sprayed into the condenser. By open steam heating of the second stage of the distillation column, AM and ammonia depart overhead, whereas aqueous methylamine is recovered as a second bottom and recycled [25]. Dangerous by-products formed by the reaction of chloramine and methylamine in the presence of base can be destroyed by adding an extra heating stage to remove by-products, mostly methylazine before work-up of the reaction product solution [26]. In this example, MMH is produced by reaction of chloramine with a one-mol excess of  $\text{MeNH}_2$  for a time  $T_1$  in an oxygen-free atmosphere in the presence of a strong base, preferably NaOH, and working up the mixture of MMH and volatile by-products by stripping followed by distillation, to give a concentrated aqueous solution of MMH. The novelty is that, before the reaction mixture is worked up, it is first heated to 343–373 K (70–100 °C) for a time  $T_2$  such that  $T_2/T_1$  is greater than 10 (pref. 50–100), in the absence of oxygen and keeping the pH above 13.5, so that the unwanted by-products are partly or completely removed.

A comparison of the traditional Raschig process with the rarely cited Thiele method for production of MMH showed that with a modern method of benzalazine preparation the Thiele method may be more suitable than the Raschig process for pilot plants with production of more than 1000 kg MMH/year [27].

## 1.2 Other Methods for Alkylhydrazine Production

Methyl-, ethyl-, *n*-propyl-, isopropyl-, *n*-butyl-, isobutyl-, and *tert*-butyl-hydrazine have been obtained in good yields (55–71%) by reaction of chloramine with the corresponding primary amines [28]. The reaction products were isolated and identified as their sulfates. The addition of gelatin to the reacting mixture was essential in obtaining good yields just as with the fundamental Raschig reaction. The minimum amount required for a good MMH yield was determined in a series of experiments and found to be 0.3 g/200 mL of 0.16-M chloramine solution. The reaction was generally carried out with an excess of methylamine, and a  $\text{CH}_3\text{NH}_2:\text{H}_2\text{NCl}$  ratio of at least 8 was required for a 64% yield. Increasing the ratio above 8 did not improve the MMH yield significantly.

Monoalkylhydrazines with a functionalized alkyl group, for instance, allylhydrazine, can be obtained from chloramine, alkali, and an excess of primary amine in a stirred, two-phase continuous flow reactor [29].

### 1.2.1 Preparation of MMH Using the Urea Process

The urea process for the preparation of hydrazine can also be modified for MMH synthesis: *N*-methylurea and sodium hydroxide dissolved in water and reacted with 5% sodium hypochlorite solution at 278 K give MMH in a 70% yield [30].

The formation of alkylhydrazines from substituted urea proceeds via two different mechanisms: **(1)** a mechanism analogous to Hofmann carboxamide conversion and **(2)** via an intramolecular aminating reaction, which passes through a diaziridinone as an intermediate [31].

The methylurea process gained renewed attention when the US Air Force sponsored a series of programs to identify new production processes that would yield both MMH and UDMH from one and the same plant, but would not use poisonous *N*-nitrosamines [32]. The first step of the urea process involves the preparation of monomethylurea or dimethylurea, which is then converted to the corresponding hydrazine by a reaction with sodium hypochlorite. Several processes to obtain the methylated ureas needed as starting materials have been described: reaction of amines (primary or secondary for MMH or UDMH) with phosgene, urethane, or cyanate will eventually provide the methylureas. A more economical route is substitution of one amino group in urea with methylamine or dimethylamine. This can be done in either anhydrous medium or in aqueous solution. A process design analysis and preliminary plant layout for a plant producing 454 metric tons/year (1 million lb/year) of MMH and UDMH each was conducted for the aqueous urea/amine process, but no additional work was carried out because the capital cost of the urea process was greater than for any of the other candidate processes [33].

*N*-Methyl-*N*-methoxyurea or *N*-methyl-*N*-hydroxyurea hydrolyze with concentrated alkali and yield MMH [31]. Following a different route, if urea is chlorinated to dichlorourea and reacted with ethylamine, at first 1,6-diethylbiurea will be obtained, which can then be converted to alkylhydrazines [34].

Chlorination of methylurea with *tert*-butyl hypochlorite gives *N*-methyl-*N*-chlorourea, which melts at 350 K. If this compound is slowly added to 50% aqueous sodium hydroxide in an ice bath, a 26% yield of MMH is obtained [35]. The reaction between *N*-methyl-*N*-chlorourea and NaOH may even proceed in the dry state by pyrolysis at 473 K, but the yields are rarely better than 26% [36].

The reaction of chloramine with monomethylurea has been shown to yield MMH and several side products, including formaldehyde monomethylhydrazone, 1,1-dimethylhydrazine, 1-methyl-3-methylene-1-triazene, methanol, and 1-methyl-triazene,  $\text{CH}_3\text{NHNHNH}_2$ , originating from the further oxidation of monomethylhydrazine with chloramine [37]. Reaction of chloramine with the sodium salts of aliphatic carboxamides such as *N*-methylacetamide gives the corresponding acethydrazide, which can be hydrolyzed to give MMH [38].

### 1.2.2 Preparation of MMH in Non-Aqueous Systems

Production of MMH or UDMH in aqueous systems requires multi-step separations of products from the reaction mixtures and the water solvent. In order to avoid the energy-intensive distillation process for separating water and MMH, processes in non-aqueous solvents have been examined as alternate processes. The Sisler process, using chloramine in non-aqueous systems, is attractive, but has not yet been used on an industrial scale. If chloramine is allowed to react with undiluted liquid ammonia or amines, a large ratio of amine to chloramine (typically 400:1) must be maintained to obtain a profitable yield of hydrazines [39]. Instead of using extreme mixture ratios, dilution with inert solvents can possibly lead to more economical operations. Reactions were carried out with either KOH or potassium methylate dissolved in methanol or in the presence of a fixed base.

In non-aqueous solvents (ether, xylene, methanol, diglyme), chloramine does not react with methylamine, in contrast to the ready chloramination of ammonia, dimethylamine, or MMH [40, 41]. However, when chloramine was fed into a solution of methylamine in methanol in the presence of a “fixed” base, such as KOH or  $\text{CH}_3\text{ONa}$ , the formation of some MMH could be observed, although the yield in laboratory experiments was very poor. The poor MMH yield was caused by the preferential reaction of chloramine with MMH rather than methylamine. Three different mechanisms for the reaction of chloramine with ammonia or amines have been proposed. Hydroxylamine as an intermediate is unlikely because it has not been detected during hydrolysis of chloramine and because no MMH results from mixing hydroxylamine and methylamine [42]. A bimolecular displacement of chlorine from

chloramine by amine or ammonia [43] should not be dependent on the presence of a fixed base. Although this mechanism may work for ammonia or dimethylamine chloramination, the reaction of methylamine and chloramine in the presence of fixed bases proceeds most likely by the formation of imide radicals, as proposed by Audrieth and co-workers [44]:

If chloramine is fed into a mixture of methylamine and MMH in a non-aqueous solvent without a strong base, the MMH is destroyed and the methylamine survives unchanged. Similarly, when bubbling chloramine gas through liquid methylamine without a solvent or fixed base, MMH is obtained in a yield of only 49% [45]. However, in the presence of alkali, chloramine reacts preferentially with the fixed base, thus not only allowing the survival of MMH but even resulting in the synthesis of additional MMH from methylamine and an intermediate. The yield of MMH or other monoalkylhydrazines prepared by the anhydrous Sisler process [46–48] can be improved if a tertiary amine such as triethylamine is used to tie up the hydrogen chloride formed in the reaction [49].

By-products from the MMH or UDMH production by reaction of chloramine with methylamine or dimethylamine have been analyzed using a gas chromatography-mass spectrometry (GC-MS) system with a 6-ft column packed with Carbowax 20M or Carbowax B [50]. Peaks identified in the MMH product mix are unreacted methylamine,  $\text{H}_3\text{CN}=\text{NH}$  or  $\text{H}_2\text{C}=\text{N}-\text{NH}_2$ , MMH, UDMH, AM, and  $(\text{CH}_3)_2\text{N}-\text{N}=\text{CH}_2$ . Similarly, the UDMH reaction products contained unreacted dimethylamine, UDMH, AM, and two unidentified peaks,  $\text{C}_4\text{H}_{10}\text{N}_2$  and  $\text{C}_2\text{H}_7\text{N}_3$  (all listed in sequence of retention times).

Instead of chloramine, hydroxylamine-*O*-sulfonic acid also gives MMH by reaction with methylamine and similarly gives UDMH on reaction with dimethylamine [51]. The reaction with methylamine may be written as:

Besides MMH and methylammonium sulfate, some water and methanol are formed as by-products. The reaction is best carried out in diglyme as a solvent. Typical MMH yields are 55%, based on the amount of  $\text{H}_2\text{NOSO}_3\text{H}$  used. In the latter case, when reacting hydroxylamine-*O*-sulfonic acid with dimethylamine to make UDMH, water and 1,1,4,4-tetramethyl-2-tetrazene were formed as by-products, presumably by oxidation of UDMH. This presumption was confirmed by reacting UDMH with excess  $\text{H}_2\text{NOSO}_3\text{H}$  under the conditions of UDMH synthesis.

### 1.2.3 Preparation of MMH by Direct Alkylation of Hydrazine

It was stated in the introduction to this section that direct methylation of hydrazine is not economical. It is still true that the methylation is uneconomical, but it is not impossible. On special occasions, such as the synthesis of isotope-labeled methylhydrazines, the direct methylation (using  $\text{CD}_3\text{I}$ ) may still be a preferred method [52]. Separation of the reaction mixture by preparative chromatography gave 56.1%  $\text{CD}_3\text{NHNH}_2$ , 42.4%  $(\text{CD}_3)_2\text{NNH}_2$ , and 1.5%  $\text{CD}_3\text{NHNHCD}_3$ .

Methylation of hydrazinium(1+) chloride or hydrazinium(2+) chloride in methanol with methyl chloride in an autoclave at 393 K, 1200 kPa for 2 h can lead to MMH chloride in a yield of 99% [53–55]. Hydrazine hydrate can be used as the base to free the MMH and the resulting hydrazinium chloride solution can be used as starting material for continued methylation [56]. Methanol instead of methyl chloride can be used as the methylating agent if 85% phosphoric acid in concentrated hydrochloric acid is used as the catalyst [57]. The reaction conditions were rather severe (4 h in an autoclave at 403 to 408 K). The MMH yield was 32.6% with 95% selectivity. Addition of hydrazine hydrate to higher alkyl bromides under stirring gives monoalkylhydrazines in yields up to 93% [58], but this method does not work well for methylhydrazine and the MMH yield is only in the vicinity of 26%.

Direct alkylation of hydrazine or hydrazinium sulfate with dimethyl sulfate gives only a mixture of methylhydrazines that need to be separated by distillation if the mixture can be used as a hypergolic fuel [59]. A laboratory method was used for the preparation of MMH and UDMH by direct methylation of hydrazine with dimethyl sulfate [60]. The relative quantities of MMH and UDMH obtained can be varied by altering the molar ratios of dimethyl sulfate to hydrazine. Small amounts of symmetrical dimethylhydrazine and trimethylhydrazine can also be formed as byproducts in this reaction. The methylation procedure was employed to manufacture several hundred pounds of MMH and UDMH for distribution to various agencies for their test programs in the 1950s.

Methylhydrazine can be prepared by methylating hydrazine or hydrazinium(1+) chloride or hydrazinium(2+) chloride with methyl chloride and/or methanol/hydrochloric acid mixture under pressure. This is done by reacting the mixture resulting from the methylation with an organic base having a  $\text{p}K_{\text{a}}$  value of greater than 7 and a boiling point above 393 K (120 °C), and separating by distillation MMH in a high boiling fraction from the reaction mixture. The high boiling fraction is optionally subjected to further distillation and the amine can be recycled [61–63].

### 1.2.4 Preparation of MMH by Indirect Alkylation of Hydrazine

According to a patent [64], hydrazine and acetone are reacted first to form the acetone hydrazone  $(\text{CH}_3)_2\text{C}=\text{N}-\text{NH}_2$  in a 94% yield. The hydrazone boils at 406–408 K (271–275 °F) and is distilled for purification, then alkylated with dimethyl sulfate to give MMH sulfate in a 72% yield, which melts at 414 K when recrystallized from ethanol. The

sulfate can then be decomposed with diethylenetriamine (which is a stronger base) to give an MMH yield of 67%.

### 1.3 Removal of Water in MMH Manufacturing

Anhydrous MMH can be obtained by continuous distillation of aqueous solutions to which seven parts of a less volatile amine such as hydrazine or ethylene diamine for each part of water have been added. In this azeotropic system, MMH of 99.8% purity will come off at the top of the column [65]. The auxiliary fluid (with all the water in it) is withdrawn from the bottom of the column and must be fractionated in a separate setup.

The separation of MMH (as well as UDMH) from water by selective permeation through membranes and pervaporation has been investigated, but it is not known if it has been used already for the production of any of these fuels. Measurements of diffusion and sorption coefficients of MMH and water in ethyl cellulose membranes were made from the reduced sorption curves to determine the overall selectivity of the membrane [66]. Desorption of MMH hydrate from ethyl cellulose has been attributed to polymer relaxation phenomena. These studies showed that the ethyl cellulose membrane can be used for prolonged periods in MMH and, as such, is suitable for the separation of MMH/water solutions.

Ethyl cellulose membranes have been selected for the separation of hydrazine and MMH solutions by pervaporation based on an extensive study of the overall mass transfer resistance experienced by the permeants [67]. The resistance values were quantitatively estimated by changing the membrane thickness and calculating the corresponding flux. Owing to its lower sorption and fewer interactions, the membrane showed least desorption resistance toward water and thus it is permselective with respect to water. Results of pervaporation selectivity obtained in the separation of water/hydrazine and water/MMH mixtures at azeotropic compositions have been correlated. Higher sorption of MMH and hydrazine did not result in preferential separation, in spite of lower membrane resistance. Experimental results clearly showed that desorption resistance and diffusivity were predominant over the respective solubilities. To confirm the reasons for these phenomena, Fourier transform infrared (FTIR) spectra and DSC thermograms of membranes soaked in pure hydrazine, MMH, water, or hydrazine hydrate were compared.

The desalted reaction aqueous liquor of MMH from a typical Raschig process contains only ~2 mass-% MMH, which also forms an azeotrope with water at an MMH concentration of 35 mass-%. Removal of water to obtain pure MMH using conventional separation methods such as distillation is hazard prone and requires much steam. The potential of membrane-based pervaporation techniques has been investigated for enriching aqueous solutions of MMH [68]. Ethyl cellulose membranes gave promising

results and were resistant to chemical attack by MMH. The effect of operating parameters such as feed concentration and membrane thickness on flux and selectivity were evaluated and aging studies have been carried out to determine the useful life of the membrane in the MMH solution. Polyphenylene oxide membranes were synthesized for dehydration of MMH and UDMH and the effect of feed concentration, membrane thickness, and permeate pressure on permselectivity was investigated [69].

The existence of an azeotrope in the binary system MMH/H<sub>2</sub>O prevents the separation by simple distillation and limits the separation possibilities [70]. An alternative, suitable for continuous flow production units, would be distillations in overpressure or under reduced pressure. Unfortunately, the definition and the development of such processes imply knowledge of experimental data, which are very often lacking. The modeling of the vapor phase compositions represents an advantageous alternative as it allows the selection of the additives and an optimization of the conditions of extraction. Auxiliary fluids were sought that facilitate the separation of MMH and water, and ethylenediamine (EDA) was one such candidate auxiliary fluid. A quasi-ideal model was applied to the predictive calculation of liquid/vapor equilibria of the system H<sub>2</sub>O/EDA [71]. The phase diagram was described by the existence of an azeotrope that disappeared under pressure. A perfect correlation was observed between the calculated results and those of the experiment for the five pressures of the binary system H<sub>2</sub>O/EDA studied. There was a limiting pressure, of 180 kPa, above which the azeotrope phenomenon was no longer observed. Next, the liquid–vapor equilibria of the ternary system H<sub>2</sub>O/EDA/MMH were calculated. The phase diagram was characterized by the existence of a diazotrophic spindle whose projection in the compositions plane separated the system into two distinct distillation fields. This is favorable for the extraction of anhydrous MMH from its azeotropic aqueous solution. Indeed, the continuous distillation of a mixture with a well-defined composition leads to anhydrous MMH at the head of the column and azeotrope H<sub>2</sub>O/EDA at the column bottom. EDA can be dehydrated by distillation under pressure and the anhydrous amine can be recycled continuously.

#### 1.4 Regeneration of Out-of-Specification MMH

At one time during the height of the Space Shuttle program, the White Sands Test Facility (WSTF) had more than 3000 gallons of MMH with a non-volatile residue (NVR) concentration in excess of the specification limit in storage. The MMH had been collected in tanks for several years for future disposition. Rather than dispose of unusable MMH, the feasibility of decontaminating and regenerating the propellant was studied as a cost-effective and environmentally friendly alternative [72]. The NVR was analyzed by FTIR and the spectrum showed that the NVR is a mixture of organic compounds with nitrogen–hydrogen and carbon–hydrogen bonds. After evaluation of several sep-

aration techniques (filtration, adsorption, distillation), distillation was selected as the separation technique. Scaling up from a bench-top distillation unit to a pilot-plant scale distillation unit required careful planning and repeated analysis of the purified MMH [73]. The bench-top distillation unit was able to reduce NVR contamination levels of 12 to 25 mg/L to a level of 0.1 to 0.2 mg/L.

### 1.5 Nitrosation Methods for the Preparation of MMH

The nitrosation of amines leading to the nitrosamine intermediate, followed by reduction with hydrogen, is normally practiced for secondary amines on the way to unsymmetrical dialkylhydrazines only (see the following section). Nitrosation of primary amines is possible if one amine hydrogen is first protected by acetylation, preparing *N*-methylacetamide (AcNHMe) as an intermediate, which is then nitrosated with sodium nitrite and acid. The nitrosamine can be reduced electrolytically in acid solution. The acetylmethylhydrazine is then hydrolyzed and MMH can be recovered by extractive distillation. Recovery of MMH of 69% based on a AcNHMe starting reactant has been reported [74]. Methylhydrazine was obtained in a 25.8% yield by the reduction of *N*-nitrosomethylamine with hydrogen gas over Pd-C catalyst at 2.06 MPa [75]. The need for an increased supply of MMH arose only after the hydrazine (UDMH) industry in the US had already learned its lessons from the production of UDMH via the troublesome nitrosamine process. Consequently, MMH production by way of nitrosamines was never developed to the pilot-plant or even industrial-scale production process level owing to the concern about the toxicity of the nitrosamine intermediates.

### 1.6 Natural Occurrence of Methylhydrazine

Methylhydrazine occurs naturally as a hydrolysis product of a mushroom glucoside gyromitrin, which has been the cause of numerous mushroom poisoning incidents [76–78].

## 2 Physical Properties of MMH

Physical properties of MMH are summarized in Table 2. Additional sources of physical properties of MMH are in the USAF Propellant Handbook, Hydrazine Fuels [79] (from which much information was extracted and was used in the compilation of this section), manufacturer's product data sheets [80], and material safety data sheets.

**Table 2:** Physical properties of methylhydrazine.

| Property                                     | SI units                                   | Other units                                                                     |            |

Note: Physical properties are listed at 298 K unless otherwise stated

Data sources: [22, 81, 82]

## 2.1 Vapor Pressure of MMH

Vapor pressure data for MMH as a function of temperature were compared and graphed in Figure 2 for a moderate temperature range. Vapor pressure of MMH as a function of higher temperature ranges is shown Figure 3, where the curve was forced through the normal boiling point.

The vapor pressure of MMH based on data from Aerojet General Corp [83], and Aston et al. [81] can be described by the following curve-fitted equation:

$$\log p = 7.11158 - \frac{1104.5711}{T} - \frac{152227.7}{T^2}$$

where  $p$  is the vapor pressure in mm Hg and  $T$  is the temperature in kelvin. This equation is valid between 265 and 360 K. It would indicate a standard MMH boiling point of 360.8 K (189.8 °F). Another reported boiling point is 360.6 K (189.5 °F) [84]. A more recent source [85] determined the vapor pressure of MMH as:

$$\ln p = 16.749949 - \frac{2776.4399}{T} - \frac{314983.3}{T^2}$$

**Figure 2:** Vapor pressure of methylhydrazine as a function of temperature, moderate temperature range. (Reproduced and modified from [79].)

where  $p$  is the vapor pressure in mmHg and  $T$  is the temperature in kelvin. The vapor–liquid equilibria of the binary system  $\text{CH}_3\text{NHNH}_2/\text{H}_2\text{O}$  were investigated from 27 to 108 kPa using a Swietoslawski-type ebulliometer [86]. From the results obtained, the modeling, in terms of associations, of the Gibbs free energy of mixing at 101.35 kPa for the liquid phase of this system enabled one to explain the observed non-ideality of the solution and to give a picture of the strong interactions existing in the mixtures, considered to be chemical associations by hydrogen bonds. This information is needed to explain some physical properties of the liquid phase, such as molar volumes, viscosity, static permittivity, and dielectric relaxation times over the whole concentration range.

Vapor pressure between the boiling point and the critical point can be represented by the following equation [79, 83]:

$$\log P = 4.5106 - \frac{1355.07}{T} - \frac{98237.8}{T^2}$$

**Figure 3:** Vapor pressure of methylhydrazine as a function of temperature, high temperature range. (Reproduced and modified from [79])

where  $P$  is the pressure in atm and  $T$  is the temperature in kelvin. In SI units ( $P$  in kPa), these equations convert to (for 273–360 K) [87–90]:

$$\log P = 6.2638 - \frac{1104.57}{T} - \frac{152227.06}{T^2}$$

where  $P$  is the pressure in kPa and  $T$  is the temperature in kelvin. And for the higher temperature range of 360–580 K the following equation can be used:

$$\log P = 6.5163 - \frac{1355.07}{T} - \frac{98237.8}{T^2}$$

Vapor pressure and sublimation pressure measurements of MMH were extended to low temperatures below the freezing point [91]. The data between 207 and 350 K can

be represented by:

$$\log P = 9.181621 - \frac{1065.025088}{T} - \frac{158905.5445}{T^2}$$

where  $P$  is the vapor pressure in pascal and  $T$  is the temperature in kelvin.

The vapor pressure data from Aston et al. 1951 for the range 275.11–298.32 K can be expressed by an Antoine equation:

$$\log_{10}(P) = 3.96787 - [1115.19/(T - 81.502)]$$

where  $P$  is the pressure in bar and  $T$  is the temperature in kelvin.

Vapor pressure measurements below 383 K could be expressed by the curve-fitted equation [92]:

$$\ln P = 19.153 - 5516.3/T + 103742.19/T^2$$

where  $P$  is the pressure in kPa and  $T$  is the temperature in kelvin. The maximum deviation of this curve from literature data was 7%. The heat of vaporization derived from the slope of this vapor pressure curve was 40.9 kJ/mol, similar to the 40.36 kJ/mol reported by Aston [81].

## 2.2 Equation of State of MMH

The accurate knowledge of the vapor pressure of MMH and other propellants is important for the assessment of flammability, explosion, and toxicity hazards at rocket test sites and in spacecraft. In an effort similar to previous/parallel calculations with various equations of state for anhydrous hydrazine, the Peng–Robinson and Soave–Redlich–Kwong (SRK) equations of state (EOS) for MMH were tested for thermodynamic consistency and the property data (critical properties, fugacity coefficients, and vapor pressure values) [89, 93]. In a side-by-side comparison, both the Peng–Robinson and the SRK EOS were then used to calculate vapor pressure values that were compared with published experimental data and vapor pressure correlation values. The Peng–Robinson EOS gave a better fit for hydrazine, and the SRK EOS gave a better fit for MMH. It was not stated which vapor pressure data from which source were used for this exercise. Equations of state, critical properties, and vapor–pressure correlations for hydrazine and MMH were used to show the importance of utilizing the most accurate vapor pressure values, and a safety analysis was performed on a hypothetical hazardous fluids test cell that needed to be purged to remove toxic vapors. The analysis showed the effect that a  $\pm 5\%$  difference in the initial vapor pressure can have on determining the length of time it takes a cell to be flushed out with air in order to meet the toxicity limits permissible for personnel to re-enter the contaminated area.

In another example, the SRK EOS was used to calculate real fluid isentropic (near adiabatic) compression temperature for the fuel/ullage gas mixtures. The isentropic final temperature  $T_2$  after compressing an ideal gas sample from  $P_1$  to  $P_2$  is:

$$T_2 = T_1 \left( \frac{P_2}{P_1} \right)^{\frac{\gamma-1}{\gamma}}$$

where  $\gamma = C_p/C_v$ . For real gases and MMH vapors,  $C_p$  and  $\gamma$  vary with temperature. The EOS was inserted to calculate compression temperature as a function of compression ratio. Starting with MMH vapor at its room temperature vapor pressure, compression ratios near 150 would be required to heat the vapor to the autodecomposition temperature of MMH in nitrogen (about 530 K). Similar calculations were made for helium, nitrogen, and mixtures of carbon monoxide, carbon dioxide, and water vapor in contact with MMH. It is assumed that the mixture of carbon monoxide, carbon dioxide, and water vapor was supposed to simulate the exhaust gas of a pyrotechnic charge in a pyrovalve blow-by situation.

In continuing to try to find the best-fitting EOS for MMH under rapid compression situations, the SRK EOS was again used for computing isentropic compression temperatures of MMH vapor [94]. It was shown that there can be a significant difference between treating MMH as a real fluid and as an ideal gas. Using the SRK EOS, a table of thermodynamic properties was computed for MMH, both saturated liquid and saturated vapor, and applied to isentropic compression or expansion of two-phase mixtures, e.g., liquid–vapor, of MMH. The use of an EOS to calculate vapor pressure reversed the previous application of the equation which required equality of the fugacity coefficients. For a given temperature, the pressure was adjusted until the computed liquid and vapor fugacity coefficients were equal. Application of the SRK EOS to the low temperature regime for MMH resulted in a consistent set of data. By comparing liquid and vapor phase fugacity coefficients, using the SRK EOS, which was previously determined to be a good representation of the phase behavior of MMH, it was possible to adjust low pressure vapor pressure data to achieve thermodynamic consistency. Using the adjusted vapor pressure data, a pseudo-Mollier diagram,  $S$  vs.  $\ln T$ , was constructed for MMH using an orthobaric calculation and applied to calculations of isentropic compression or expansion of MMH. The shape of the liquid–vapor coexistence envelope curve was thermodynamically consistent. Future work would need to perform a closer examination of the behavior of MMH near the critical point, including scaling law considerations.

To calculate the vapor pressure during the vaporization of MMH at very high pressures, such as in a rocket combustion chamber, requires a different set of equations [95]. Under these conditions, MMH transitions from evaporation to decomposition.

### 2.3 Vapor-Phase Composition of MMH/H<sub>2</sub>O Mixtures

The vapor-phase composition and partial pressure above dilute solutions of hydrazine or MMH in water is of practical interest for several reasons: **(1)** for the recovery of hydrazines from dilute solutions by distillation, **(2)** for predicting the downwind hazard from evaporating hydrazine spills, and **(3)** for designing water spray scrubbers for the removal of MMH vapors from depressurizing storage tanks vent gases or tank purge gases. Henry's law constants were determined for hydrazine and MMH in water as part of a vapor scrubber design study [96]. Measurements were performed at 283, 293, and 303 K on 1, 0.5, 0.25, and 0.1% solutions, buffered at pH 7 and unbuffered. The effect of 1 and 2% added sodium chloride was also evaluated. The addition of salt reduces the constant  $k$  slightly. Henry's law states that the partial pressure of constituent  $A$  above a mixture is proportional to the molar fraction  $X$  of the ingredient  $A$  in the liquid phase:

$$p_A = kXA.$$

The values of  $k$  were found to be relatively independent of concentration (Table 3). A plot of  $\log k$  versus  $1/T$  (reciprocal absolute temperature) gave the following heats of vaporization in kJ/mol (kcal/mol):

|           | Buffered at pH 7         | Unbuffered               |
|-----------|--------------------------|--------------------------|
| Hydrazine | 36 kJ/mol (8.6 kcal/mol) | 39 kJ/mol (9.3 kcal/mol) |
| MMH       | 25 kJ/mol (5.9 kcal/mol) | 31 kJ/mol (7.4 kcal/mol) |

The  $k$  values for hydrazine or MMH are only 5% of what would be expected from ideal mixtures based on Raoult's law. This indicates that there is strong solvent-solute interaction for both hydrazines that reduces their concentrations in the vapor phase. MMH and water form an azeotrope containing 42% MMH.

**Table 3:** Henry's law constants for aqueous solutions of methylhydrazine.

| Temperature<br>K | Henry's law constant $k \times 10^4$ ,<br>buffered pH 7<br>Concentration, mass-% |     |     | Henry's law constant $k \times 10^4$ ,<br>unbuffered<br>Concentration, mass-% |     |     |

|                  | 1.0                                                                              | 0.5 | 0.1 | 1.0                                                                           | 0.5 | 0.1 |
| 283              | 1.4                                                                              | 1.6 | 1.6 | 13                                                                            | 15  | 15  |
| 293              | 1.4                                                                              | 1.7 | 1.8 | 26                                                                            | 25  | 29  |
| 303              | 3.0                                                                              | 3.1 | 3.4 | 33                                                                            | 33  | 34  |

Data source: [96]

There is a pinch point at the azeotrope concentration, making further concentration difficult. Using a longer distillation column results in only a small improvement of product concentration [32]. For sizing an azeotrope distillation column that takes in a 2% MMH solution and delivers a 42% MMH solution, model distillations were performed under laboratory conditions. A separation factor was calculated from the composition of the overhead and the reboiler. The relative volatility  $\alpha$  can then be calculated based on the number of theoretical plates in the column. The volatility  $\alpha$  and the optimal number of theoretical plates can be determined graphically. Once the 42% MMH intermediate is obtained, the remaining water has to be removed by the addition of concentrated caustic and an extractive distillation in the finishing column. An equation for the activity coefficient of MMH volatility in water mixtures takes the form:

$$\log y_c = \frac{-0.9172}{\left[1 + \frac{0.9172X_c}{0.3273(1 - X_c)}\right]^2}$$

where  $X_c$  is the MMH molar fraction in the liquid phase [97]. Measurements of the equilibrium liquid and vapor compositions vs. temperatures at 101 kPa (1 atm) total pressure for the non-ideal system MMH/H<sub>2</sub>O showed a rather large deviation from ideal liquid–vapor solution behavior [85]. The solution model attributes the non-ideality to the formation of chemical association species that obey Henry's law in terms of actual solution equilibrium molar fractions. The unassociated MMH and water are assumed to obey Raoult's law in terms of actual molar fraction composition. Similar measurements were performed for UDMH-containing systems. Figure 4 shows a maximum boiling azeotrope of MMH and water and shows the two lines, the liquid composition and the vapor composition, to be tangent to one another at 378.83 K (105.68 °C) and  $\chi_{\text{MMH}} = 0.2837$ . If one plots the excess Gibbs free energy of mixing, the curve shows a rather large negative free energy. For the H<sub>2</sub>O (= A)/MMH (= B) system, both A : B = 1 : 1 and 1 : 3 association clusters prevail in the mixture.

The Ferriol data illustrated in Figure 5 are better than those in Figure 4 because the graph in Figure 5 is based on eight data pairs instead of only five, as in Figure 4 (but the graph is more confusing because it contains additional data for three different pressures).

The water used in the process of MMH preparation and separation is critical for the quality of MMH. The vapor–liquid equilibrium of MMH/H<sub>2</sub>O binary system was measured at 101 kPa and the influence of MMH/H<sub>2</sub>O/electrolyte ternary systems was examined [98]. Electrolytes remarkably raised the volatility of MMH and changed the vapor–liquid equilibrium of the MMH/H<sub>2</sub>O binary system. The vapor–liquid equilibrium of MMH/H<sub>2</sub>O/NaCl and MMH/H<sub>2</sub>O/NaOH ternary systems were studied by experiments. Salt effects of electrolytes were correlated using a salt effect coefficient method and a solvation method. NaOH had a greater effect on the MMH/H<sub>2</sub>O binary system than NaCl. Salt effects of these two electrolytes were compared.

**Figure 4:** Equilibrium liquid and vapor compositions at 1atm total pressure vs. molar fraction methylhydrazine. (Republished and modified from [85], with permission from ©1987 Springer Nature BV; permission conveyed through Copyright Clearance Center Inc.)

The vapor pressure of a mixture of 72mass-% MMH and 28% water can be calculated from the equation:

$$\log P = 7.8894 - \frac{1852}{T}$$

where  $P$  is the pressure in mm Hg and  $T$  is the absolute temperature [99].

Vapor-liquid equilibria of the MMH/water system can be predicted by computational chemistry. Predictions for MMH/water isobaric vapor-liquid equilibria and vapor phase compositions from quantum mechanical and Grand Equilibrium and force field model computational methods were compared with measured data from Ferriol et al. [86] or Cohen-Adad et al. [85] and were in moderately accurate agreement [100]. Figure 6 depicts the vapor-liquid equilibrium of MMH + water at ambient pressure. It

Legend: + water at 0.1013 MPa; (x) experimental data by Ferriol et al. [86]; (+) experimental data by Cohen-Adad et al. [85]; (•) Elts simulation data with  $\xi = 1.3$ ; solid line Peng–Robinson EOS with  $k_{ij} = -0.197$

can be seen that the experimental data by Ferriol et al. [86] and by Cohen-Adad et al. [85] are quite similar; however, they differ near the azeotropic region. Like aqueous hydrazine, this mixture is azeotropic, having a temperature maximum. In this case, the azeotropic point lies at an MMH molar fraction of  $\chi_{\text{MMH}} \approx 0.25$  mol/mol. The experimental data by Ferriol et al. [86] at 372.55 K and  $\chi_{\text{MMH}} = 0.476$  mol/mol were taken to adjust the binary parameter of the molecular model ( $\xi = 1.3$ ) and of the Peng–Robinson EOS ( $k_{ij} = -0.197$ ). In the water-rich region, to the left of the azeotropic point in Figure 6, vapor–liquid equilibrium computer simulations were not feasible because of sampling problems [101]. Considering the substantial experimental uncertainties, the data sets from all three approaches agreed very favorably.

If MMH is made by methylation of hydrazine or hydrazine hydrate, in the presence of an excess of hydrazine or hydrazine hydrate, the reaction mixture may consist of MMH, unreacted hydrazine (hydrate), and water. This ternary mixture forms an azeotrope that is difficult to separate by simple distillation [102].

Methylhydrazine vapor and water vapor associate in the vapor phase to form clusters in which the frequencies of hydrogen bond infrared (IR) bands are shifted. A theoretical study of the geometry and molecular parameters of the methylhydrazine–hydrate complex analyzed two geometries, considering the interaction between water in: **(1)** a lone nitrogen pair assisted by a  $\text{CH}_3$  group; and **(2)** the nitrogen of the  $\text{NH}_2$  group [103]. These geometries were examined by examining the formation of ( $\text{N}\cdots\text{H}$ ) hydrogen bonds, which were characterized using charge transfer, as well as topological parameters derived from Quantum Theory of Atoms in Molecules calculations. A trimolecular system may be formed by methylhydrazine and two attached water molecules.

## 2.4 Density of Methylhydrazine

The density of methylhydrazines is generally below that of hydrazine itself. This is due to reduced association of the molecules in the liquid phase (less hydrogen bonding). The density of MMH has been measured by numerous authors and companies, including Horvitz and Osborg [104], Ahlert and Shimalla [105], Aerojet General Corp. [83], and Barger et al. [106]. The temperature dependence of the density of MMH can be reproduced by:

$$\rho = 1.15034 - 9.3949 \times 10^{-4} T$$

where  $\rho$  is the density in  $\text{g/cm}^3$  and  $T$  is the temperature in kelvin. Other authors obtained the following relationship, giving slightly higher densities [107]:

$$\rho = 0.7917 + 1.9396 \times 10^{-3} T - 5.564 \times 10^{-6} T^2$$

where  $\rho$  is the density in  $\text{g/cm}^3$  and  $T$  is the temperature in kelvin. Density data from several different sources at moderate temperatures are shown in Figure 7.

**Figure 7:** Density as a function of temperature, saturated liquid methylhydrazine; moderate temperature range. (Reproduced and modified from [79].)

The density of the saturated liquid at elevated temperatures above the normal boiling point has to take into consideration the compressibility of the liquid at higher pressures. Data reported for pressures other than the saturation pressure should thus be normalized to the saturation pressure. Normalized density data from Aerojet [83] and the Handbook [79] for the density of liquid MMH between the normal boiling point and the critical point are shown in Figure 8.

Attempts to predict density, EOS, second virial coefficients, and critical point properties of MMH from theoretical computations have not always produced accurate results [100, 101].

**Figure 8:** Density as a function of temperature, saturated liquid methylhydrazine; elevated temperature range. (Reproduced and modified from [79].)

## 2.4.1 Density of MMH Mixtures

### 2.4.1.1 Density of Mixtures of Methylhydrazine with Water

The density of MMH/H<sub>2</sub>O mixtures at 295 K increases linearly from 0.873 at 0% H<sub>2</sub>O to 0.955 g/cm<sup>3</sup> at 28% H<sub>2</sub>O. The rate of density increase is less steep for water concentrations above 28%. The density of the 28% water/MMH mix can be calculated from:

$$\rho = 0.975 - 0.00086 t$$

where  $\rho$  is the density in g/cm<sup>3</sup> and  $t$  is the temperature in °C. The density of the same mix as a function of temperature and pressure can be calculated from:

$$\rho = 0.975 - 8.6 \times 10^{-4} t + 3.3 \times 10^{-6} P$$

where  $\rho$  is the density in g/cm<sup>3</sup>,  $t$  is the temperature in °C, and  $P$  is the pressure in psia [99]. If one plots the results of this equation on graph paper, the curves are very close to each other and the pressure effect is not very pronounced (at least within this range in the order of hundreds instead of thousands of psia).

Density and viscosity of MMH/water mixtures were measured over the entire range of compositions and between 148 and 293 K [107], as summarized in Table 4 (density) and Table 6 (viscosity) and as illustrated in Figure 9 (density) and Figure 13

**Table 4:** Density of methylhydrazine/water mixtures.

| Temperature, K     | 293.15                     | 278.15 | 268.15 | 258.15 | 248.15 |

| 1.0000             | 0.8835                     | 0.9010 | 0.9120 | 0.9213 | 0.9300 |

Data source: [107]

**Figure 9:** Density of methylhydrazine/water mixtures. (Graph created by Schmidt 2016, based on data from [107].)

(viscosity). Vapor pressure, density, and viscosity data applied to a chemical association model indicated that the solutions contain a MMH monohydrate, a trihydrate, and an MMH dimer [85, 107, 108].

#### 2.4.1.2 Density of Mixtures of Methylhydrazine with Hydrazine

Hydrazine/MMH blends containing 14, 35, 60, and 90% hydrazine were tested as rocket propellants and densities of the four blends were measured from 260 to 325 K [109]. The temperature dependence of the density of three selected hydrazine/MMH mixtures can be represented by the three equations in Table 5.

**Table 5:** Temperature dependence of the density of three selected hydrazine/methylhydrazine mixtures.

| Composition, mass-% $\text{N}_2\text{H}_4$ | Density $\rho$ in $\text{g}/\text{cm}^3$ , temperature $T$ in kelvin |
|--------------------------------------------|----------------------------------------------------------------------|
| 30.24                                      | $\rho = 1.1998117 - 0.000967625T$                                    |
| 56.15                                      | $\rho = 1.23459405 - 0.000965816T$                                   |
| 78.04                                      | $\rho = 1.24102194 - 0.00090115T$                                    |

Data source: [105]

More detailed data on density of MHF-3 as a function of temperature and pressure are presented in Section 13.2.1.1.

#### 2.4.1.3 Density of Ternary MMH/ $\text{N}_2\text{H}_4$ / $\text{H}_2\text{O}$ Mixtures

Mixtures of MMH, hydrazine, and water are of interest as monopropellants and as fuels. The densities of MMH, hydrazine, and water mixtures are illustrated in Figure 10. There is a maximum of density around the point that corresponds to hydrazine hydrate.

#### 2.4.1.4 Density of Ternary MMH/ $\text{N}_2\text{H}_4$ /HN Mixtures

Mixtures of MMH, hydrazine, and hydrazinium nitrate (HN) are of interest as monopropellants and as fuels. The density of MHF-5A, a monopropellant composed of 68% MMH, 13%  $\text{N}_2\text{H}_4$ , and 19% HN, is  $0.996 \text{ g}/\text{cm}^3$  ( $62.2 \text{ lb}/\text{ft}^3$ ) at 298 K (77°F) and  $0.968 \text{ g}/\text{cm}^3$  ( $60.4 \text{ lb}/\text{ft}^3$ ) at 328 K (130°F). The density of MHF-5B (58% MMH, 23%  $\text{N}_2\text{H}_4$ , 19% HN) at the same two temperatures is 1.002 and  $0.974 \text{ g}/\text{cm}^3$  respectively [110].

The densities of mixtures of MMH, hydrazine, and HN are illustrated in Figure 11. The lowest densities are in the MMH corner of the graph. Densities increase with increasing hydrazine and/or HN content.

**Figure 10:** Densities of methylhydrazine, hydrazine, and water mixtures. (Reproduced and modified from [79].)

**Figure 11:** Densities of ternary mixtures of methylhydrazine,  $\text{N}_2\text{H}_4$ , and hydrazinium nitrate. (Reproduced and modified from [79].)

## 2.5 Compressibility of Methylhydrazine

Sonochemistry is a new discipline in the study of chemical reactions. Transient temperatures up to 5000 K and pressures of 500 atm can occur during the adiabatic compression (collapse) of cavitating microcavities. Under these conditions, ther-

modynamically unstable substances such as hydrazine and MMH are susceptible to decomposition. Hydrazine in pure form or in dilute aqueous solution (100 ppm) decomposes smoothly to nitrogen and hydrogen when irradiated by a 600-W ultrasonic probe at 20 kHz [111]. Dilute solutions of MMH decompose at about the same rates as hydrazine; however, the products are more complex, yielding methyl amine, methyl alcohol, and ammonia.

For MMH, no direct measurements of isothermal compressibility have been reported, but isothermal compressibilities  $\beta_i$  can also be calculated from density data at different pressures:

$$\beta_i = \frac{1}{V} \frac{dV}{dP}$$

A set of MMH densities has been reported for temperatures from 340.6 to 543 K at two different pressures [83, 106]. From these data a compressibility–temperature dependence function of:

$$\begin{aligned}\beta_i \left( \frac{\text{cm}^2}{\text{kg}_f} \right) &= 2.133 \times 10^{-6} T - 6.727 \times 10^{-4} \\ \beta_i \left( \frac{\text{m}^2}{\text{N}} \right) &= 2.174 \times 10^{-11} T - 6.857 \times 10^{-9}\end{aligned}$$

can be calculated. However, as density was measured at only two pressures for each temperature, the equation is not very accurate.

Data compiled by Rocketdyne over a wider temperature range gave the following equation for the temperature dependence of the adiabatic compressibility for MMH (we are repeating the original equations in units of  $\text{cm}^2/\text{kg}_f$  in spite of their non-standard units):

$$\beta_a(\text{MMH}) \left( \frac{\text{cm}^2}{\text{kg}_f} \right) = 3.0413 \times 10^{-5} - 2.1258 \times 10^{-7} T + 9.194 \times 10^{-10} T^2$$

where  $T$  is the temperature in kelvin.

## 2.6 Velocity of Sound in Liquid Methylhydrazine

The velocity of sound in liquid MMH is 1548 m/s at 298 K and the velocity of sound in MMH vapor is 310.2 m/s at 361 K [90]. The velocity of sound in liquid MMH and its temperature dependence can be calculated by using the following equation:

$$c_{\text{MMH}} = 2711.6 - 3.903T$$

where  $c$  is the velocity of sound in m/s and  $T$  the temperature in kelvin.

It is planned to determine the density by the buoyancy of a floater and to determine the velocity of sound in MMH along the saturation curve at temperatures up to

the critical point and pressures up to 200 bar by measuring the resonant frequency in a high-pressure bomb made of titanium with sapphire windows [112].

## 2.7 Viscosity of Methylhydrazine

The viscosity of MMH has been measured by numerous authors and companies, including Horvitz and Osborg [104], Barger et al. [106], Horvitz [113], and Horvitz et al. [114]. The data were obtained at different temperatures, but agreement within the overlapping range at 298 K is quite good. The curve in Figure 12 was calculated using the following formula, which is based on the combined data from multiple sources:

$$\log \mu = -7.9944 + \frac{6123.96}{T} - \frac{1.7458 \times 10^6}{T^2} - \frac{1.8509 \times 10^8}{T^3}$$

where  $\mu$  is the dynamic viscosity in cPs and  $T$  is the temperature in kelvin.

**Figure 12:** Dynamic viscosity versus temperature for liquid methylhydrazine. (Reproduced and modified from [79].)

### 2.7.1 Viscosity of MMH/H<sub>2</sub>O Mixtures

The viscosity of MMH/H<sub>2</sub>O mixtures passes through a maximum at 28 mass-% H<sub>2</sub>O. This mixture corresponds to a 1:1 molar ratio of MMH:H<sub>2</sub>O, indicating formation of a hydrate compound [99]. The viscosity of the MMH hydrate at 277.5 K (40 °F) is 8 cPs, much higher than that of water (2.5 cPs) or MMH (1.3 cPs). The viscosity of the MMH hydrate mix increases steeply as it approaches 255 K (0 °F). At that temperature the vis-

cosity is 35 cPs. Viscosity of MMH/water mixtures was measured over the entire range of compositions and between 148 and 293 K, as summarized in Table 6 and as illustrated in Figure 13 [107].

**Table 6:** Viscosity of methylhydrazine/water mixtures.

| Temperature, K     | 293.15         | 278.15 | 268.15 | 258.15 | 248.15 |
|--------------------|----------------|--------|--------|--------|--------|
| Molar fraction MMH | Viscosity, mPs |        |        |        |        |
| 0.0000             | 1.01           | 1.53   | 2.16   | 3.34   | 6.45   |
| 0.0514             | 1.53           | 2.55   | 3.67   | —      | —      |
| 0.1003             | 2.35           | 4.18   | 6.46   | 11.44  | —      |
| 0.1615             | 3.54           | 7.18   | 11.79  | 24.83  | 52.28  |
| 0.2017             | 4.51           | 9.30   | 16.16  | 37.62  | 84.39  |
| 0.2563             | 5.58           | 12.15  | 22.30  | 50.90  | 124.95 |
| 0.3030             | 6.00           | 13.52  | 26.47  | 58.85  | 165.14 |
| 0.3482             | 5.90           | 13.32  | 26.89  | 61.50  | 167.20 |
| 0.4048             | 5.50           | 12.28  | 24.33  | 54.67  | 140.14 |
| 0.4408             | 4.91           | 10.68  | 20.84  | 42.43  | 118.51 |
| 0.5008             | 4.07           | 7.88   | 14.95  | 30.62  | 78.79  |
| 0.6034             | 2.98           | 5.53   | 9.40   | 17.58  | 41.96  |
| 0.6873             | 2.16           | 3.48   | 5.80   | 10.15  | 23.36  |
| 0.8036             | 1.56           | 2.51   | 3.67   | 5.97   | 10.63  |
| 0.8917             | 1.22           | 1.66   | 2.34   | 2.88   | 5.27   |
| 1.0000             | 0.96           | 1.15   | 1.59   | 2.18   | 3.19   |

Data source: [107]

The viscosity of MMH/water mixtures peaks near an MMH molar fraction of 0.33. The peak is very pronounced at the lower temperatures. These data indicate that the solutions contain a MMH monohydrate, a trihydrate, and an MMH dimer. One mixture of 72% MMH and 28% water was of particular interest, as it was used as a fuel in the SURVEYOR space probes that soft-landed on the Moon [99]. The viscosity of this fuel blend as a function of temperature is tabulated in Table 7.

## 2.7.2 Viscosity of Methylhydrazine/Hydrazine Mixtures

The viscosity of MHF-3 is described in Section 13.2.1.4.

## 2.7.3 Viscosity of Ternary Mixtures with Methylhydrazine

The viscosity of MHF-5B, a monopropellant consisting of 58% MMH, 23%  $\text{N}_2\text{H}_4$ , and 19% HN at 233, 298, and 328 K, is 38, 1.98, and 1.1 cPs, respectively [110]. Additional properties of MHF-5B are listed in Section 13.3.1. The absolute viscosities of ternary mixtures of MMH,  $\text{N}_2\text{H}_4$ , and  $\text{N}_2\text{H}_5\text{NO}_3$  are illustrated in the triangular chart in Figure 14. The viscosities of these mixtures increase with increasing HN content.

**Figure 13:** Viscosity of methylhydrazine/water mixtures. (Chart created by Schmidt 2016, based on data from [107].)

**Table 7:** Kinematic viscosity of 72% methylhydrazine/28% water fuel blend.

| Temperature |       |       | Kinematic viscosity |
|-------------|-------|-------|---------------------|
| K           | °C    | °F    | cSt                 |
| 237.1       | −36.0 | −32.8 | 225.0               |

## 2.8 Surface Tension of Methylhydrazine

Knowledge of surface tension of methylhydrazine is of both theoretical and practical interest because (1) the surface tension can be used to derive parachor data and gain information on the molecular structure of these compounds and (2) the design of fuel tanks for retaining fluids by capillary forces in the weightlessness of outer space requires the knowledge of the surface tension and wetting angles.

The surface tension of MMH at 298 K is  $3.383 \times 10^{-4}$  N/m [90]. The surface tension of MMH as a function of temperature can be expressed by the following equations:

$$\sigma_{\text{MMH}} \left( \frac{\text{dyn}}{\text{cm}} \right) = 63.480 - 0.09944T$$

$$\sigma_{\text{MMH}} \left( \frac{\text{N}}{\text{m}} \right) = 0.06348 - 9.9944 \times 10^{-5}T.$$

**Figure 14:** Absolute viscosities of ternary mixtures of methylhydrazine,  $\text{N}_2\text{H}_4$ , and hydrazinium nitrate. (Reproduced and modified from [79].)

The surface tension data of MMH listed in Table 8 and illustrated in Figure 15 can be calculated by the analytical expression [115, 116]:

$$\gamma = 65.8 \times 10^{-3} \left( 1 - \frac{T}{606} \right)$$

where  $\gamma$  is the surface tension in N/m and  $T$  the temperature in kelvin. The denominator under  $T$  is the critical temperature of MMH in kelvin. The equation can also be expressed in logarithmic form:

$$\gamma = 65.2 \times 10^{-3} \left( 1 - \frac{T}{585.2} \right)^{0.937}$$

where  $\gamma$  is the surface tension in N/m and  $T$  the temperature in kelvin. Both the linear and the logarithmic expressions reproduce the experimental results equally well.

Whereas there are numerous data on MMH viscosity and surface tension, only very few data can be found on the angle of wetting of MMH in contact with various surfaces. Such wetting angle data are needed for the design of surface tension retention propellant management devices for propellant tanks for space use in zero-gravity environments (see Section 9.1). The wetting angle is very dependent not only on the chemical composition of the metal, but also on the method of surface treatment prior to the test and on surface changes that may occur with prolonged wetting by MMH or exposure to MMH vapor.

**Table 8:** Surface tension of methylhydrazine.

| Compound | Temperature |      | Surface tension       |        |
|----------|-------------|------|-----------------------|--------|
|          | K           | °C   | N/m × 10 <sup>3</sup> | dyn/cm |

**2.9 Thermal Conductivity of Methylhydrazine**

The thermal conductivity of liquid MMH as a function of temperature is represented by the following equations [117]:

$$\lambda = 3.4025 \times 10^{-4} + 2.200 \times 10^{-6}T - 4.545 \times 10^{-9}T^2$$

where  $\lambda$  is the thermal conductivity in  $\text{cal cm}^{-1} \text{K}^{-1} \text{s}^{-1}$  and  $T$  is the temperature in kelvin. The same data in SI units give the equation:

$$\lambda = 1.4236 \times 10^{-1} + 9.2048 \times 10^{-4} T - 1.9016 \times 10^{-6} T^2$$

where  $\lambda$  is the thermal conductivity in  $\text{W m}^{-1} \text{K}^{-1}$  and  $T$  is the temperature in kelvin. The accuracy of these equations was estimated to vary from  $\pm 1.5$  to  $\pm 4\%$  depending on where in the range 256–325 K the data are calculated. The scatter of data is evident if one looks at the data points in Figure 16.

**Figure 16:** Thermal conductivity of liquid methylhydrazine. (Reproduced and modified from [79].)

The MMH used in this study was of 99.2% purity and contained 0.7% water. Single-point data for the thermal conductivity of liquid MMH were reported as  $0.25 \text{ W m}^{-1} \text{K}^{-1}$  ( $1.72$  British thermal units [BTU]  $\text{in. ft}^{-2} \text{h}^{-1} \text{°F}^{-1}$ ) [90]. The thermal conductivity of MMH was calculated and estimated to be of the order of  $0.027 \text{ W m}^{-1} \text{K}^{-1}$ .

## 2.10 Heat-Transfer Coefficient of Methylhydrazine

Knowledge of heat-transfer characteristics of methylhydrazine is of importance in the design of injectors and cooling jackets for rocket engines and gas generators using this

propellant. An excellent summary of heat flux limits of storable rocket propellants, including hydrazine, MMH, UDMH, and their mixtures, is provided in [118]. More specifically, heat transfer and burnout flux studies were made in MMH and MHF-5 at subcritical and supercritical pressures [119–123]. Fifty-five heat transfer tests were conducted with electrically heated CRES-347 stainless steel and Inconel 718 tubes within the following ranges of conditions: 1.71 to 27.3 MPa (250 to 3960 psia) pressure, 5.38 to 62.3 m/s (17.7 to 205 ft/s) flow velocity, 232 to 426 K (–42 to 308 °F) bulk temperature, and heat fluxes up to 81 MW/m<sup>2</sup> (49.6 BTU in.<sup>–2</sup> s<sup>–1</sup>). Normal nucleate boiling was observed with MHF-5 and MMH at subcritical pressures and at wall temperatures slightly greater than the saturation temperature. Steady-state film boiling was also observed with MMH. The burnout heat flux, that is the heat flux where a transition from nucleate boiling to film boiling occurred, correlated with the product of velocity and subcooling. A reduction in burnout heat flux, attributed to viscous effects, was observed with MHF-5 and MMH at low bulk temperatures. This behavior was noted in previous investigations with other propellants and a fairly general correlation for predicting this phenomenon was established. Burnout-like conditions were observed with both propellants at supercritical pressures. It was found that the heat flux at which this condition developed, termed the ultimate heat flux, could be predicted reasonably well with conventional forced convection expressions in conjunction with a maximum wall temperature of 644 K (700 °F). Forced convection heat transfer with MMH and MHF-5 can be described using the Hines Correlation:

$$\text{Nu}_b = 0.005 \text{Re}_b^{0.95} \text{Pr}_b^{0.4}.$$

Heat transfer coefficients significantly higher than given by the Hines Correlation were measured at low bulk temperatures with both propellants at subcritical and supercritical pressures. These high coefficients were due to thermal entrance effects and correlated with a modified form of the Hines Correlation:

$$\text{Nu}_b = 0.005 \text{Re}_b^{0.95} \text{Pr}_b^{0.4} (F_{L/D})$$

where

$$F_{L/D} = 1.0 + 0.018 \frac{\text{Pr}}{(L/D)^{\frac{1}{2}}}$$

for  $L/D \leq 10$  and  $3.8 \leq \text{Pr} \leq 141.3$ . Subcritical forced convection heat flux data for MMH are illustrated in Figure 17.

After previous futile – and in part disastrous – attempts to use anhydrous hydrazine as a cooling medium in regeneratively cooled rocket engines [124], nobody now seriously considers anhydrous hydrazine to be a suitable fuel in regeneratively fuel-cooled engines. MMH is thermally more stable than N<sub>2</sub>H<sub>4</sub> and proved to be a suitable regenerative coolant.

Two sets of data are available for the ultimate heat flux of MMH as a function of flow, pressure, and bulk and wall temperatures [118]. The ultimate heat flux  $q_{ul}$  ranged

**Figure 17:** Subcritical methylhydrazine forced convection data. (Reproduced and modified from [121, 122].)

from  $7.52 \times 10^6$  to  $1.60 \times 10^7$  W/m<sup>2</sup> (4.6–9.8 BTU in.<sup>-2</sup> s<sup>-1</sup>) at 1.5–2.2 MPa and fluid temperatures from 327 to 421 K. Development testing with MMH in the regeneratively fuel-cooled Surveyor thrust chamber revealed that decomposition of MMH under transient thrust extremes degraded the cooling characteristics of the engine [99]. Addition of 28% water to MMH improved the heat-transfer characteristics and cooling capability of the fuel and reduced flame temperature on the hot side of the combustion chamber wall.

Limitations of the upper heat flux and cooling capability of MMH are evident in small bipropellant rocket engines operating at high pressures. Heat transfer calculations showed that beyond a certain operating regime, MMH cooling is insufficient.

## 2.11 Critical Constants of Methylhydrazine

In some extreme cases of heat transfer to hydrazines at high pressures and high temperatures the conditions may approach the critical point and reach supercritical conditions where totally different physical laws govern fluid properties and heat transfer.

Although this regime is fairly well explored for water, liquid hydrogen, and other thermally stable fluids, very little information is available on hydrazines under supercritical conditions. The critical constants of hydrazine(s) are very difficult to determine because the liquid usually undergoes decomposition before the critical point is reached. Critical constants for methylhydrazine are summarized in Table 9. Most of these data are calculated from other physical and thermodynamic properties measured under non-critical conditions [125].

**Table 9:** Critical constants of methylhydrazines in comparison with those of hydrazine.

| Compound        | Critical temperature, K | Critical pressure, MPa | Critical density, g/cm <sup>3</sup> | References |
|-----------------|-------------------------|------------------------|-------------------------------------|------------|
| MMH             | 567                     | 8.1                    | 0.17                                | [1]        |
| MMH             | 585                     | 8.21                   | 0.29                                | [83]       |
| MMH             | 585                     | 8.21                   | 0.29                                | [90]       |

| Hydrazine       | 653                     | 1.469                  | —                                   | [128]      |

## 2.12 Solubility of Pressurant Gases in Methylhydrazine

The solubility of gases in methylhydrazine(s) is of interest in the application of methylhydrazine(s) as rocket propellants. In many cases the propellants are fed into the decomposition or combustion chamber not by a pump, but by a pressurant gas, usually nitrogen or helium [129]. Unless a gas-tight, impermeable diaphragm is employed, the fuels become saturated with the pressurant gas. Heat-transfer characteristics of the gas-saturated liquids are significantly different from those of the pure liquid because dissolved gas bubbles are released prematurely, blocking effective heat transfer and sometimes causing the rocket chamber wall to burn out. Release of dissolved gasses and loss of thermal margin cause two-phase flow. Two-phase flow has a higher pressure drop than a clean single-phase flow. Solubility–pressure relationships are governed by Henry’s law:

$$\chi = KP$$

where  $\chi$  is the molar fraction of dissolved gas,  $P$  is the partial pressure of the gas, and  $K$  is the solubility constant. If the pressure is entered in units of atmospheres, then the unit of  $K$  is atm<sup>−1</sup>.

The solubility of common pressurant gases (nitrogen, argon, helium) in methylhydrazines has been determined by Chang, Gokcen, and Poston [130–132]. These data

have been reviewed and converted to other units published in solubility data reference works [133]. The values of  $K$  as a function of temperature can be read from Figure 18. The unit of  $K$  is  $\text{atm}^{-1}$ . These data were taken at relatively low pressures, much lower than typical rocket operating pressures. It would be inaccurate to extrapolate these data to higher pressures.

**Figure 18:** Gas solubility in liquid methylhydrazine as a function of temperature. (Reproduced and modified from [22] as adapted from [130].)

The equilibrium constant  $K_i$  for the pressurant gas equilibrium between the gas phase and the dissolved state is the molar fraction of solute  $i$  divided by its partial pressure  $P_i$  over the equilibrated solution. Its temperature dependence can be expressed by:

$$\log K_i = \frac{A}{T} + B$$

where  $A$  and  $B$  are constants and  $T$  is the absolute temperature in kelvin. Table 10 gives a summary of  $A$  and  $B$  constants for three different gases dissolved in MMH in comparison with other hydrazines.

Raw data for the solubility of nitrogen in liquid MMH are summarized in Table 11.

**Table 10:** Solubility of pressurant gases in methylhydrazine in comparison with other hydrazines.

| Gas             | Propellant                    | A    | B      | Solubility at 101 kPa, ppm by mass |       |
|-----------------|-------------------------------|------|--------|------------------------------------|-------|
|                 |                               |      |        | 273 K                              | 298 K |
| He              | MMH                           | −393 | 1.6586 | 1.6                                | 2.1   |

STP = standard temperature and pressure

Data source: [134]

From the data in this table, a solubility constant  $\alpha$  can be calculated from [134]:

$$\alpha = 2.582 \times 10^{-3}P + 1.3 \times 10^{-7}P^2$$

where  $\alpha$  is the solubility constant  $\alpha$  in terms of milliliters of nitrogen at STP dissolved in 1 g of MMH and  $P$  is the pressure in psia, or

$$\alpha = 17.80P + 6.18P^2$$

where  $\alpha$  is the solubility constant  $\alpha$  in terms of milliliters of nitrogen at STP dissolved in 1 g of MMH and  $P$  is the pressure in kPa.

It is often difficult to achieve reproducible pressurant gas saturation for development and qualification testing of rocket engines where release of pressurant gases is suspected to cause cavitation, premature transition to different boiling mechanisms in fuel-cooled rocket engines, loss of thermal margin, and burnout. Just pressurizing the run tank and waiting is often not an acceptable solution. Methods for accelerating pressurant gas saturation by sparging, recirculating the liquid, and actively pumping or stirring have been evaluated, but none is satisfactory. Dissolved gas measurements on propellant samples taken from large tanks never show the same amount of saturation as that that can be achieved in the laboratory using a glass apparatus. Table 12 is a comparison of helium saturation in MMH normalized to 1720 kPa (250 psig) and 298 K (77 °F) and shows a wide range of data reported in the literature.

**Table 12:** Comparison of helium saturation in methylhydrazine normalized to 1720 kPa (250 psig) and 298 K (77 °F).

Data source: [137]

Computer models have been developed to predict the amount of pressure lost owing to pressurant gas solubility in MMH or dinitrogen tetroxide (NTO), also with respect to launch safety criteria on Space Shuttle Space Transportation System (STS) Orbit Maneuvering System (OMS) and Reaction Control System (RCS) propellant tanks [138]. Sometimes thin-walled tanks holding liquids have to be pressurized to a minimum pressure to have sufficient stiffness during launch acceleration and they would buckle if too much pressurant gas was absorbed because gas absorption was not figured into the launch preparations check list. Comparison of predicted and measured pressurant gas pressure decay during the prelaunch hold period due to gradual saturation of propellant showed acceptably good agreement [139, 140]. Unexpected pressure changes occur in bipropellant blowdown systems and may cause a shift in the oxidizer : fuel ratio and resultant performance losses or hotter-than-nominal operation with chamber burnouts [141, 142]. Some systems are pressurized immediately prior to launch. If some of the propellant is consumed right away shortly after launch, the effects of gas solubility will become less noticeable with a larger ullage. But with small ullages at

the beginning of the blowdown cycle, and if the system is not used right away, it may take weeks for saturation to be achieved and the tank pressures may be imbalanced. The same may apply to pairs of tanks of the same propellant connected by a manifold. If the two tanks are at different temperatures, propellant distribution may be uneven and cause unexpected shifts in the center of gravity of the upper stage rocket or the satellite (“thermal pumping”).

Dissolved pressurant gases and the degree of gas saturation may affect the performance (ignition delay, injector boiling, dribble volume expulsion) of bipropellant rocket engines [143]. Pressurant gas evolution during refueling transfer of helium-saturated propellants from supply vehicles to satellites in space may complicate metering the amount of propellant transferred under zero-g conditions [144, 145].

It was planned to accurately measure the pressure decay after pressurization of the ROSETTA MMH tank with helium, but the ullage warmed up significantly during pressurization, which accelerated helium absorption even before the pressurization process was completed [146]. The ROSETTA tanks had a relatively large ullage volume, compared with those in a previously tested smaller satellite, METEOSAT Second Generation (MSG), where pressure decay predictions using the Knowles method were more accurate. It was not possible to determine how much helium had dissolved already during the pressurization process in the ROSETTA tank. Pressure decay measurements are complicated by the fact that satellites and upper stages prior to launch are not in a thermostatted constant temperature environment and ambient temperature fluctuations result in pressure fluctuations. By knowing the speed of the pressure decay, it would be possible to compute the necessary initial elevated filling pressures that would then drop to the desired pressure at launch time. Measured pressure decay data from the ESA CLUSTER spacecraft and a number of American satellites were used to predict the pressure decay in MMH-propellant tanks of the ESA MSG and ROSETTA spacecraft [147].

The Japanese H-II Transfer Vehicle (HTV) has four main thrusters (500 N) used for orbit control, and 28 RCS thrusters (110 N) used for reaction control. HTV has multiple engine and long propellant supply lines that make its operation and surge pressure spikes dependent on propellant pressurant gas saturation level. A visual bubble point technique and GC were used to determine the helium saturation level prior to ground level testing of the propulsion system [148].

Owing to helium solubility in propellants (MMH and NTO), tank pressure may decrease for several days after initial tank pressurization on the ground prior to launch. A model is necessary to predict the pressure loss. Conventional models had been designed with the assumption that the tank was static. However, in the case of the Japanese HTV, propellant sloshing occurred by movement of the HTV between buildings on the ground prior to launch. Tank pressure loss in HTV tanks could not be predicted by the conventional model because of the sloshing. An improved numerical

solubility model expresses the influence of sloshing on helium solubility by solving the vertical distribution of helium concentration in the stratified tank contents [149].

## 2.13 Thermochemical Properties of Methylhydrazine

Thermochemical properties such as heat capacity, enthalpy of formation, heat of combustion, heat of vaporization, and other thermal characteristics are necessary for calculation of the useful energy derived from MMH in a number of industrial applications.

There are several summary publications dealing with thermochemistry and molecular structures of alkylhydrazines, also in their relation to azo and azoxy compounds derived by the oxidation of alkylhydrazines [150, 151]. See also [112, 152].

### 2.13.1 Heat Capacity of Methylhydrazine

Whereas heat capacity data for ideal vapors can be calculated from IR spectroscopic data, heat capacity determination of liquids and solids depends on calorimetric measurements, which are usually less accurate. Heat capacities are important for the calculation of temperature changes in hydrazines during industrial processes. They are also required for conversion of standard enthalpies and entropies of formation to other temperatures (other than 298 K).

Data on the heat capacity of solid and liquid MMH are available from [81, 117]. Combination of the two sets of data for MMH lead to the following equations:

$$c_p = 0.6528 - 1.7284 \times 10^{-5} T + 3.9142 \times 10^{-7} T^2$$

where  $c_p$  is the heat capacity in  $\text{cal g}^{-1} \text{K}^{-1}$  and  $T$  is the temperature in kelvin. The same data in SI units give the equation:

$$c_p = 2.7313 - 7.2316 \times 10^{-5} T + 1.6377 \times 10^{-6} T^2$$

where  $c_p$  is the heat capacity in  $\text{J g}^{-1} \text{K}^{-1}$  and  $T$  is the temperature in kelvin. This equation may be used for liquid MMH up to 397 K (see also [153]). Other summary publications recommend the following equations for the heat capacity of liquid MMH [90]:

$$C_p(\text{J mol}^{-1} \text{K}^{-1}) = 125.6 - 3.3265 \times 10^{-3} T + 1.1383 \times 10^{-4} T^2, \quad T \text{ in K}$$

and for MMH vapor:

$$C_p(\text{J mol}^{-1} \text{K}^{-1}) = 9.4708 + 0.2495 T - 1.495 \times 10^{-4} T^2 + 3.537 \times 10^{-8} T^3, \quad T \text{ in K.}$$

Some of Aston's historical heat capacity data for MMH from [81] are summarized in Table 13.

Table 14 gives a comparison of the heat capacities of three liquid methylhydrazines.

**Table 13:** Heat capacity of solid, liquid, and vapor methylhydrazine.

### 2.13.2 Enthalpy of Formation of Methylhydrazine

Exact knowledge of thermodynamic data, including enthalpy of formation, free energy of formation, and entropy is important for the calculation of the theoretical performance of alkylhydrazines in a number of practical applications, such as rocket engines. In addition to those from calorimetric determinations, these data are usually obtained from IR, Raman, or microwave spectroscopic observations and quantum mechanical or statistical thermodynamics calculations of the molecular vibrations. This requires knowledge of the structure of the molecules, which is discussed in more detail in Section 2.16.

The upper heat of combustion of MMH at 305.6 K (32.5°C) was measured as 1303 to 1305 kJ/mol (311.5 to 311.8 kcal/mol) in a calorimeter, after corrections for a contaminant assumed to be UDMH [155]. In the same apparatus, a heat of combustion of hydrazine was measured as 629.68 kJ/mol (150.497 kcal/mol). A later measurement in the same apparatus gave the heat of combustion of MMH as 1304.2 kJ/mol (311.711 kcal/mol) at 303 K [156].

The upper heat of combustion once reported by Cole and Gilbert in 1951 [157] actually was given to them by Aston and is the same as that reported by Aston in 1952 [81]. The enthalpy of formation of MMH calculated by Cole and Gilbert [157] based on the heat of combustion given to them by Aston was +54.14 kJ/mol (+12.94 kcal/mol) and this number was different than the generally accepted number published a few decades later.

The upper heat of combustion of MMH was measured at 303.15 K and found to be 1304 kJ/mol = 311.711 kcal/mol [158]. If this number is corrected to the heat of combustion at 298 K, a value of 1306 kJ/mol = 312.112 kcal/mol would be obtained. Using the known heats of formation of CO<sub>2</sub>(G) and (H<sub>2</sub>O)L, the standard enthalpy of formation of MMH can be calculated:  $(\Delta H)_f^{298} \text{MMH(L)} = +54.83 \text{ kJ/mol} = +13.106 \text{ kcal/mol}$ . Note that this is a positive number, indicating that MMH is capable of exothermic decomposition into its elements or lower molecule fragments such as ammonia and methane.

Enthalpies of formation of liquid methylhydrazines are derived mostly from calorimetric measurements of the heat of combustion, but literature data obtained by these methods are not always consistent. Thermochemical data for vapors of methylhydrazines can be derived from spectroscopic measurements or molecular orbital quantum chemical calculations. Because of the lack of consistency of the thermochemical data derived from calorimetric measurements and reported in the literature, a consistent set of data has been calculated at the G4 level for methylhydrazines in the vapor state, also in comparison with methylamines from which they are made [159]. The computed values from two different sources are compared with experimental values in Table 15 and show generally good agreement. When looking at the changes in enthalpy of formation caused by the introduction of a methyl group replacing a hydrogen atom, it is interesting to compare this effect as it applies to ammonia going to methylamines and hydrazine going to methylhydrazines.

**Table 15:** Computed and experimental values for enthalpies of formation of methylhydrazine vapors.

| Compound                                                          | Enthalpy of formation, kJ/mol |                  |                  |

Data source: [161] and references listed therein

The standard enthalpy of formation of an equimolar mix of MMH and water containing 28 mass-% H<sub>2</sub>O is −239.7 kJ/mol (−57.3 kcal/mol) [99]. This is 4.33 kJ/mol below the mathematical sum of heats of formation of the ingredients. This fuel blend was used in the SURVEYOR lunar landers.

### 2.13.3 Enthalpy of Fusion of MMH

The heat of fusion of MMH, corrected for pre-melting was determined as 10.4202 ± 0.0012 kJ/mol (2.4905 ± 0.0003 kcal/mol) [81]. The decreasing molar heat of fusion of methylhydrazines with progressive methylation is an indication of reduced hydrogen bonding in the series N<sub>2</sub>H<sub>4</sub>, MMH, and UDMH.

### 2.13.4 Enthalpy of Evaporation of MMH

The heat of evaporation of MMH was not only derived from the vapor pressure curve, but also directly measured by Aston et al. 1951. The average of five determinations gave  $(\Delta H)^{298}_{\text{vap}} = 40.36 \text{ kJ/mol} = 9.648 \text{ kcal/mol}$ , compared with 40.693 kJ/mol = 9.726 kcal/mol calculated from the vapor pressure equation. The heat of vaporization

at the normal boiling point is of more practical importance. It has been calculated to be  $37.21 \text{ kJ/mol} = 8.894 \text{ kcal/mol}$  with a Trouton constant of 24.6. Other sources gave the heat of vaporization at 364 K as  $36.12 \text{ kJ/mol}$  [162]. The heat of vaporization derived from the slope of a vapor pressure curve was  $40.9 \text{ kJ/mol}$ , [92] similar to  $40.36 \text{ kJ/mol}$  reported by Aston [81]. Attempts to predict vapor pressure and enthalpy of vaporization of MMH from theoretical computations have not always produced accurate results [101].

### 2.13.5 Entropy of MMH

Entropy data for liquid and vapor MMH are summarized in Table 17. The entropy of vaporization at 298 K is  $135.39 \text{ J mol}^{-1} \text{ K}^{-1}$ . The entropy of fusion at 220.79 K is  $47.19 \text{ J mol}^{-1} \text{ K}^{-1}$ .

**Table 17:** Entropy data for liquid and vapor methylhydrazine at 298.16 K.

## 2.14 Optical Properties of MMH

This section deals with the interaction of methylhydrazines with electromagnetic radiation in the wavelength range from 100 nm to 20 cm. Correspondingly, this section is subdivided into ultraviolet (UV)/visible absorption, IR absorption, and microwave absorption. The spectra obtained in these spectral ranges are of particular interest in the clarification of the molecular structure of hydrazines and measurement of the energies of the atomic and intermolecular bonds in them. As the hydrazine N—N bond (as opposed to the azo bond N=N and its many azo dyes) is not a chromophore, there is nothing to report on light absorption of hydrazine derivatives within the visible range. The optical properties of MMH and other methylhydrazines are important for analytical applications, verifying the purity of the propellant before it is loaded into spacecraft or missiles, and detecting the presence of leaked MMH vapors in areas where it does not belong and constitutes a hazard to both equipment and personnel. Spectra of MMH enabled us to better understand the structure of this molecule and derive thermochemical properties that are important for its use as a rocket propellant.

### 2.14.1 Ultraviolet Spectra of MMH

Vacuum UV absorption coefficients for hydrazine, MMH, and UDMH were measured from 115 to 185 nm to determine interference of leaked propellants with UV sensors in space applications [165]. Vacuum UV absorption coefficients for  $\text{N}_2\text{H}_4$ ,  $\text{CH}_3\text{HNNH}_2$ , and  $(\text{CH}_3)_2\text{NNH}_2$  were measured for wavelengths between 115 and 185 nm with an estimated experimental error of  $\pm 15\%$ . The measurements were made in a hydrazine-compatible flow-cell apparatus at room temperature.

For the UV absorption of MMH at 213.9 nm a UV absorption cross-section of  $\sigma = 2489 \times 10^{-20} \text{ cm}^2/\text{mol}$  was assumed for hydrazine photolysis and autoxidation studies in the atmosphere [166, 167].

### 2.14.2 Infrared Spectra of MMH

It is common practice to describe spectra by giving wavenumbers and intensities of absorption bands. The following abbreviations are in use for describing peak heights: **vs**, very strong; **s**, strong; and **w**, weak. Wavenumbers (in  $\text{cm}^{-1}$ ) can be converted to wavelength (in  $\mu\text{m}$ ) by forming the reciprocal. A common unit for wavenumbers is reciprocal centimeters,  $\text{cm}^{-1} = \text{kayser}$ . This gives the number of wavelengths that fit into 1 cm. A chapter on IR spectroscopy could possibly also be subdivided by the experimental technique used, of which there are quite a few: transmission, reflectance, attenuated total reflectance, vapor absorption, liquid absorption, mulls, emulsions, solid films, solid matrix isolation, adsorbed state on solid surfaces, complexed state in ligand spheres, isotope substitution, Fourier transform enhanced, and many more. Almost all of these have been applied to measure IR spectra of MMH at one time or another. A separation that proved difficult was to discuss IR spectra without repeatedly referring to supporting Raman spectroscopy work, which was supposed to be summarized in a separate section, following the section on IR spectra. The two methods complement each other, and one would be well served to read both sections when looking for spectroscopic information on methylhydrazines.

The 21 normal vibrations of MMH are all expected to be IR active [168]. Apart from the three skeletal vibrations that absorb at low wavenumbers, the fundamentals listed in Table 18 are expected.

Infrared gas-phase spectra of MMH have been measured from 33 to  $4000 \text{ cm}^{-1}$  [153]. The IR and Raman spectra of MMH in the liquid state were also recorded. Absorption band assignments were made possible by isotope substitution and recording the IR and Raman spectra of  $\text{D}_2\text{NNDCH}_3$  and  $\text{D}_2\text{NNDCH}_3$ . A complete vibrational analysis based on band intensity, position, and isotopic shift could be obtained. By assuming that a symmetrical threefold cosine potential governs both rotors in MMH, rotational barriers of 15.3 and 15.6 kJ/mol (3.67 and 3.72 kcal/mol) were calculated for the methyl and amino group torsions respectively. Several of the frequencies are shifted as a result of hydrogen bonding, and the difference becomes apparent when comparing spectra obtained in the gas phase or in a frozen argon solid matrix. The monomeric

**Table 18:** Fundamental vibration modes and infrared spectra of methylhydrazine.

| Methylhydrazine                       |                              |

Data source: [168]

argon matrix N—H stretching vibrations occur at 3366, 3358, and  $3314\text{ cm}^{-1}$ , but as a result of association, they are found in the Raman spectra of the liquid at lower frequencies, 3316, 3304, and  $3258\text{ cm}^{-1}$ . The intensity of the  $3182\text{-cm}^{-1}$  line of  $\text{NH}_2\text{NHCH}_3$  has been studied as a function of temperature. The  $\Delta H^\circ$  for hydrogen bond formation was found to be  $-1749\text{ J/mol}$  ( $-418\text{ cal/mol}$ ). MMH thermodynamic functions have been calculated for the temperature range 200–3000 K on the basis of a rigid rotator, harmonic oscillator model. These fundamental rotational–vibrational assignments superseded those of Axford, Janz, and Russell [168]. Slightly different assignments of group frequencies in MMH were made based on spectra of deuterium-substituted methylhydrazines,  $\text{D}_3\text{CNHNH}_2$  and  $\text{H}_3\text{CNDND}_2$  [52].

Although most investigators only measure the location of the absorption bands on the wavenumber scale, there are only very few measurements of the absorption coefficient of MMH in the vapor state. Such measurements are necessary to determine the MMH concentration by IR absorption of the vapor, for instance, in the pressurant gas vented from bipropellant systems and fed to a scrubber. The peak absorption coefficients for two near-IR absorptions of MMH at  $6560$  and  $9620\text{ cm}^{-1}$  were measured [169]. It was difficult to establish accurate partial pressures of MMH in the dry nitrogen purge system owing to adsorption of MMH on the walls of the tubing and FTIR absorption multiple reflection cells. Dynamic and static methods were tested, but none provided better than  $\pm 20\%$  accuracy in partial pressure. The dynamic method generated MMH-saturated nitrogen by bubbling dry  $\text{GN}_2$  through liquid MMH in a thermostatted bath. The static method injected MMH from a syringe into a known volume and relied on convection for complete mixing. The peak absorption coefficient at  $6560\text{ cm}^{-1}$  was  $3.1 \times 10^{-2}\text{ cm}^{-1}\text{ atm}^{-1}$  and at  $9620\text{ cm}^{-1}$  it was  $9.7 \times 10^{-4}\text{ cm}^{-1}\text{ atm}^{-1}$ . Absorption bands located at 6560, 6423, and  $6316\text{ cm}^{-1}$  were assigned to the  $\Delta\nu = 2$  overtones of the N—H stretching fundamentals at 3317, 3245, and  $3177\text{ cm}^{-1}$ .

The IR spectra of MMH and other methylhydrazines are contained in a catalog of IR spectra for qualitative analysis of gases [170]. The far-IR spectra of methylhydrazine ( $\text{CH}_3\text{NHNH}_2$ ), deuterated methylhydrazine- $\text{C-d}_3$  ( $\text{CD}_3\text{NHNH}_2$ ), and d-methylhydrazine- $\text{N,N'-d}_3$  ( $\text{CH}_3\text{NDND}_2$ ) in the gas phase have been recorded between 370 and  $100\text{ cm}^{-1}$  with a resolution of  $0.1\text{ cm}^{-1}$  [171] (Figure 19).

The amino torsional fundamentals and several hot bands have been observed and assigned on the basis of the presence of the inner and outer skew conformers. Rotational constants have been determined from the observed K-structure arising from the amino torsional mode of the inner conformer. A potential function for the amino torsion of MMH has been calculated by using three potential coefficients. The methyl torsions in  $\text{CH}_3\text{NDND}_2$  have been assigned to the frequency region between 280 and  $255\text{ cm}^{-1}$ .

A convenient source of IR radiation for various analytical applications is the diode laser. Absorption measurements of pure hydrazine and MMH were recorded in an optical absorption cell (3 passes,  $50\text{ cm/pass}$ ) at low pressure ( $0\text{--}35\text{ Torr}$ ) using a tunable external-cavity diode laser, operating within the range from  $6350$  to  $6650\text{ cm}^{-1}$  ( $1.49$  to  $1.58\text{ }\mu\text{m}$ ) [172, 173]. Peak absorption cross-section measurements of MMH, as determined from fixed wavelength absorption measurements recorded at various pressures, were found to be  $\alpha_e/\nu = 0.152 \pm 0.003\text{ cm}^{-1}\text{ atm}^{-1}$  at  $6560\text{ cm}^{-1}$  ( $\lambda = 1524.4\text{ nm}$ ). The measurements represented the first high-resolution survey spectra of these hydrazines in the near IR. These measurements were supporting the design of a diode-laser-based leak detection system for the STS Space Shuttle launchpad.

The injectors of bipropellant engines remain filled after the engine shuts down and their unreacted contents evaporate slowly into vacuum. Thin films of hydrazine or MMH or their decomposition products that may condense on cryocooled germanium optical windows of sensors on satellites in outer space might block IR transmittance. Therefore, IR absorption spectra of thin films of frozen MMH on cold germanium windows were measured and interpreted by Fourier transform analysis [174, 175]. Thin MMH films from  $0.25$  to  $9.0\text{ }\mu\text{m}$  thick were formed on a germanium substrate at  $20\text{ K}$  (cold helium gas) or  $80\text{ K}$  (liquid nitrogen) in vacuum, and the IR transmittances

were measured by using an FTIR spectrometer [176, 177]. A dual-angle laser interference technique was used to determine the thickness and the refractive index of the thin hydrazine films. In addition, a quartz crystal microbalance was used to weigh the amount and give the average loading density. Absorption spectra of frozen MMH films on germanium windows showed a relatively strong band at  $3164\text{ cm}^{-1}$ , whereas no such band was observed in liquid MMH. Also, a splitting at  $2934$  and  $2964\text{ cm}^{-1}$  was not visible in the liquid samples analyzed by other authors. Spectra continued to be recorded while the sample warmed up from 80 K. The most significant spectral change after warm-up was the appearance of a sharp, strong absorption band at  $3340\text{ cm}^{-1}$ . This is believed to be either the  $\nu_1$  or  $\nu_2$  fundamental.

Because of the need for a controlled environment, atmospheric studies of homogeneous autoxidation of hydrazines in air have to be conducted in laboratory chambers with non-reactive walls. It has been noted that much of the oxidation occurs heterogeneously on the walls of these chambers and it was difficult to eliminate wall effects. The IR spectra of adsorbed MMH on chamber materials (silica, silica-alumina, and alumina) were recorded in an effort to find inert chamber materials. Diffuse reflectance spectroscopy of hydrazines adsorbed on silica, silica-alumina or alumina indicated that the primary surface-MMH interaction is hydrogen bonding [178, 179]. In the adsorbed methylhydrazines, the C—H stretching and methyl deformation modes are shifted to higher frequencies by 10 to  $20\text{ cm}^{-1}$  as the result of electron density changes on the adjacent nitrogen atom.

### 2.14.3 Raman Spectra of MMH

Raman spectra often supplement IR spectra in a very useful manner. In many instances a complete assignment of absorption lines to fundamental vibrations can only be made by comparing the two types of spectra side-by-side.

The Raman spectra of MMH were recorded in the liquid state [153]. Absorption band assignments were made possible by isotope substitution and recording the IR and Raman spectra of  $\text{D}_2\text{NNDCH}_3$  and  $\text{D}_2\text{NND CD}_3$ . It is quite educational to look at some of the very first, quite ancient Raman spectra of MMH, UDMH, and symmetrical dimethylhydrazine (SDMH) published in 1938 [180].

Methylhydrazine forms a hydrate and dimers that have distinctly different properties from those of anhydrous and monomeric MMH. Water/MMH mixtures were investigated by means of Raman spectroscopy for the entire concentration range at room temperature and vs. temperature for some mixtures [181]. The Raman spectra of the liquid mixtures have shown that several species coexist in solution. Spectroscopic features have been assigned to MMH dimers and MMH  $n$ -hydrates. It was shown that solvation of MMH had a major influence on the C—N—N skeleton vibrations. For highly concentrated solutions in MMH, the presence of a high percentage of MMH dimers has been confirmed. A preliminary study of the effects of temperature on some water-MMH mixtures showed that the skeleton frequencies were perturbed by cooling.

When cooled to low temperatures, MMH hydrate does not crystallize readily, but forms a glass. Raman scattering investigations were carried out in the MMH/water molecular glass-former systems, revealing different species of molecular association through characteristic hydrogen-bonding interactions [182]. A relation between fragility and dilution was proposed based on low-frequency Raman data. The ability to form hydrogen bonds was analyzed versus dilution from the temperature dependence of the frequency of stretchings associated with hydrogen bonding, and discussed in the context of the glass formation. Unusual behavior of mixtures around the eutectic composition was noted and interpreted in relation to hydrogen-bond heterogeneities. See also [180].

#### 2.14.4 Index of Refraction of MMH

The index of refraction of MMH at 298 K is  $n_D^{25} = 1.4284$ .

### 2.15 Microwave Spectra of MMH

Microwave spectra extend the IR toward very long wavelengths of the order of millimeters instead of micrometers. Because of the lesser quantum energy, microwave spectra reveal details of low-energy molecular transitions, such as individual rotation energy states and their thawing temperatures. This helps to identify molecular structures and intermolecular forces leading to adducts and dimers.

In the microwave spectrum of MMH, two rotational isomers (“rotamers”) have been observed and their spectra assigned and interpreted [183]. The ground-state rotational constants of the inner skew isomer were  $A = 36704$  MHz,  $B = 9689.7$  MHz, and  $C = 8531.9$  MHz, whereas the values obtained for the outer skew rotamer were  $A - C = 29597.2$  MHz and  $\kappa = -0.925849$ . Strong evidence for the proposed conformational assignments was obtained from dipole moment components that differed for the two rotamers. Relative intensity measurements indicated that the inner rotamer is more stable than the outer rotamer by  $293 \pm 23$  cm<sup>-1</sup>. Spectral splitting by inversion and methyl “tunneling” have also been observed. Analysis of the latter effect indicated a barrier of  $1329$  cm<sup>-1</sup> for the inner rotamer. Hyperfine splitting caused by interaction with <sup>14</sup>N nuclei could be resolved, and the quadrupole coupling constants were  $\chi_{aa} = 4.09 \pm 0.03$  MHz,  $\chi_{bb} = 0.69 \pm 0.03$  MHz, and  $\chi_{cc} = -4.78 \pm 0.04$  MHz.

The microwave spectra of the inner and outer conformers of MMH have been measured [184]. The rotational constants and the <sup>14</sup>N nuclear quadrupole coupling constants (in MHz) for the outer conformer were determined as:  $A_0 = 38091.6(3)$ ,  $B_0 = 9591.93(6)$ ,  $C_0 = 8494.42(6)$ ,  $\chi_{aa1} = 3.7(3)$ ,  $\chi_{bb1} = 0.7(4)$ ,  $\chi_{aa2} = 3.2(3)$ , and  $\chi_{bb2} = -2.5(3)$ . The values in parentheses represent estimated limits of error, and suffixes 1 and 2 represent the N nuclei with and without the methyl group respectively. The inversion motion at the N1 nucleus is found to split the rotational levels; the barrier

heights of the inversion for the inner and outer conformers were estimated to be  $1960$  and  $2480\text{ cm}^{-1}$  respectively. Far-IR spectra have been measured for the normal and  $\text{CH}_3\text{NDND}_2$  species with a resolution of  $0.1\text{ cm}^{-1}$ . The observed absorption peaks were assigned to transitions related to the N—N and N—C torsional modes. The equilibrium dihedral angles for the N—N torsion were estimated to be  $93$  and  $268^\circ$  for the inner and outer conformers respectively.

Microwave spectral data on the inversion splittings in MMH were analyzed by the use of a generalized internal-axis method [185]. Inversion tunneling parameters reproducing the observed splittings were determined through a least-squares analysis for the inner and outer conformations.

## 2.16 Molecular Structure of MMH

The molecular structure of MMH is illustrated in Figure 20.

**Figure 20:** Molecular structure of methylhydrazine

The molecular structure of MMH was described by Aston, Rock, and Isserow [158]. The bond angles are assumed to be tetrahedral, and the bond lengths are as follows:

|     |                                 |
|-----|---------------------------------|
| N—N | $1.45 \times 10^{-10}\text{ m}$ |
| N—C | $1.47 \times 10^{-10}\text{ m}$ |
| N—H | $1.04 \times 10^{-10}\text{ m}$ |
| C—H | $1.09 \times 10^{-10}\text{ m}$ |

Three different configurations have been proposed for the molecular structure of MMH, a *trans*, an *outer-skew*, and an *inner-skew* configuration [163]. Looking at the possible configurations of the MMH molecule end-on in the same direction as the N—N axis gives the three different views illustrated in Figure 21, where the solid lines indicate the bonds to the two hydrogen atoms on the terminal nitrogen and the dashed lines indicate the bonds to the central nitrogen atom.

On the basis of spectroscopic data, it was concluded that MMH exists predominantly in the skew outer form with its methyl group farthest from the hydrogens of the  $\text{NH}_2$  group. This is also supported by photoelectron spectra of MMH [186]. See Section 2.17.

**Figure 21:** End-on views of three different methylhydrazine configurations

The *cis*-barrier height hindering the N–N torsional motion in MMH is  $36.2 \pm 3.6$  kJ/mol ( $8.66 \pm 0.86$  kcal/mol), with the maximum at a torsional angle of  $359^\circ$  [164]. The *trans* barrier is only  $15.0 \pm 0.3$  kJ/mol ( $3.58 \pm 0.07$  kcal/mol) and peaks at  $197^\circ$ . In addition to obstructed rotation around the N–N axis, the impeded rotation around the C–N axis also contributes to the varying degrees of freedom that are responsible for the specific heat of the molecule [171].

Another set of *ab initio* calculations using Pulay's force method and a new normal coordinate force relaxation procedure showed that in MMH the most stable conformation is the one in which the C–N bond can interact with the adjacent lone electron pair on nitrogen [187]. The optimized parameters for bond distances, bond angles, and total energies were in moderately close agreement with experimental data.

The electron diffraction intensity of methylhydrazine  $\text{CH}_3\text{NHNH}_2$  has been measured and analyzed jointly with the rotational constants of the conformers, inner and outer [188]. The optimized geometrical parameters and the force constants of the two conformers, derived from an Self-Consistent Field Molecular Orbital (SCF-MO) calculation with a 4-31G\* basis set, were utilized in the analysis. The following bond lengths ( $r_g$ ) and angles ( $r_z$ ) were measured:  $r(\text{C}–\text{H}) = 1.115(10)$  Å,  $r(\text{N}–\text{N})_{\text{i}} = 1.433(12)$  Å,  $r(\text{N}–\text{C})_{\text{i}} = 1.463(12)$  Å,  $\angle \text{CNN}_{\text{i}} = 113.47(21)^\circ$ ,  $r(\text{N}–\text{C})_{\text{o}} = 1.466(2)$  Å, and  $\angle \text{CNN}_{\text{o}} = 109.46(15)^\circ$ , where values in parentheses represent estimated limits of error ( $2.5\sigma$ ).  $r(\text{C}–\text{H})$  is a weighted average for the inner (i) and outer (o) conformers and the difference  $r(\text{N}–\text{C})_{\text{o}} - r(\text{N}–\text{N})_{\text{o}}$  is fixed to that predicted by the calculation, 0.0353 Å.

Various computational methods have been applied to model the MMH molecule, also in comparison with the parent molecule hydrazine, and in comparison with other methylhydrazines. The MMH molecule with its two rotational axes is a challenge for modeling computations. Not all computer models give accurate representations of physical properties. Computer models need experimental data for comparison and verification. Most models need to be tweaked to get their predictions to more closely match experimental data.

A few force field parameters and models have been published for hydrazine and alkylhydrazines and validated against experimental saturated densities, vapor pressure, heat of vaporization, isobaric heat capacity, and self-diffusion coefficients. Al-

though in one case this yielded satisfactory results for the liquid density and the heat of vaporization, the vapor pressure predicted for hydrazine and its derivatives deviated significantly from experimental data [189]. The model underestimated the experimental saturated liquid density of MMH from 2.8% at 273 K to 7.7% at 450 K and the vapor pressure of MMH was on average 4% below the experimental data.

Improved molecular models for hydrazine, MMH, and UDMH were developed to study the fluid phase behavior of these compounds [101]. A parameterization of classical molecular interaction models was carried out by using quantum chemical calculations and subsequent fitting to experimental vapor pressure and saturated liquid density data. Predicted critical temperature, 606.6 K, was 22 to 40° different than the literature data. Predicted critical density, 6.53 mol/L, was totally mismatched with literature data (3.69 mol/L). Predicted critical pressure (7.66 MPa) was in close agreement with the experimental value of 8.04 MPa. To validate the molecular models, vapor–liquid equilibria for the pure hydrazines and binary hydrazine mixtures with water or ammonia were calculated and compared with available experimental data. In addition, the Henry's law constant for the physical solubility of argon, nitrogen, and carbon monoxide in liquid MMH and UDMH was computed. In general, the simulation results were in good agreement with the experimental data.

Frozen MMH crystallizes in monoclinic crystals, space group  $P2_1/c$ , with unit cell parameters of  $a = 10.043 \text{ \AA}$ ,  $b = 3.925 \text{ \AA}$ ,  $c = 7.670 \text{ \AA}$ ,  $Z = 4$ ,  $\beta = 107.28^\circ$ ,  $V = 48.9 \text{ \AA}^3$ , and  $\rho = 1.06 \text{ g/cm}^3$  [190]. When cooled quickly, MMH supercools and forms a glassy solid instead of crystallizing.

## 2.17 Photoelectron and XPS Spectra of MMH

Electron spectroscopy for chemical analysis (ESCA, synonym: X-ray photoelectron spectroscopy, XPS) is a spectroscopic method that can be applied to vapors and solid surfaces. Depending on the objective of the analysis and the range of atomic weights to be scanned, resonance lines of noble gases in the vacuum UV or monochromatic X rays (magnesium or aluminum) are used to excite photoelectrons that are then passed through a monochromator, and their energy and intensity are measured. In solid materials, only a very thin surface layer is analyzed, usually only 5 nm deep. Photoelectron spectroscopy has developed into a very useful tool for conformational analysis, and ESCA spectra permit quantitative determination of the interaction of molecular orbitals by measuring the ionization energies of various molecular valence orbitals with high precision. Different conformations are characterized by different energy states and usually show up as separate or split peaks in the ESCA spectrum. Additional data on photoionization and ionization potentials of hydrazines can be found in Section 4.3. Ionization potentials of MMH in mass spectrometers are summarized in Section 4.5.

The ESCA spectra of aliphatic hydrazines allow a conformational analysis of substituted hydrazines with C—N—N linkages [191]. There is a correlation between the torsional angle between the two lonely pairs of electrons with the splitting of the two *n*-orbitals determined from the photoelectron spectrum [192]. See also [193, 194].

The He I photoelectron spectra of unsymmetrical hydrazines  $\text{CH}_3\text{HNNH}_2$  and  $(\text{CH}_3)_2\text{NNH}_2$  have been measured and CNDO/2 calculations have been carried out, in which *gauche* (outer- and inner-skew) forms and *trans* form were taken into account for  $\text{CH}_3\text{HNNH}_2$ . It was found that non-bonding splittings in the photoelectron spectra are well reproduced by CNDO/2 calculations with *gauche* forms. Based on orbital assignments of the photoelectron spectra it was concluded that: (1) The first and second bands are due to the methylated and unmethylated nitrogen lone pairs respectively; (2) the third bands are attributed to the N—N bonding orbitals; (3) the rest of the photoelectron spectra up to 18 eV can be explained in terms of other p-type orbitals (C—N bonding,  $\text{CH}_3$  pseudo  $\pi$ , and  $\text{NH}_2$  pseudo  $\pi$ ). The ESCA-XPS spectra have been used for conformational structural analysis of molecules of hydrazine derivatives [195].

The valence shell electronic structures of MMH, 1,1-dimethylhydrazine, and tetramethylhydrazine were examined by recording threshold and conventional (kinetic energy resolved) photoelectron spectra [196, 197]. In parallel, *ab initio* calculations were performed on the three methyl substituted hydrazines. The ionization energies of the valence molecular orbitals were calculated, allowing the photoelectron bands to be assigned to specific molecular orbitals. The ground-state adiabatic and vertical ionization energies, as determined from the threshold photoelectron spectra, were  $IE_a = 8.02 \pm 0.16 \text{ eV}$  and  $IE_v = 9.36 \pm 0.02 \text{ eV}$  for MMH,  $IE_a = 7.78 \pm 0.16 \text{ eV}$  and  $IE_v = 8.86 \pm 0.01 \text{ eV}$  for UDMH, and  $IE_a = 7.26 \pm 0.16 \text{ eV}$  and  $IE_v = 8.38 \pm 0.01 \text{ eV}$  for tetramethylhydrazine. Owing to the large geometry change that occurs upon ionization, these  $IE_a$  values were all higher than the true thresholds. New heats of formation ( $\Delta H_f^\circ$ ) were proposed for the three hydrazines in the vapor state on the basis of G3 calculations: 107, 94, and 95 kJ/mol for MMH, 1,1-dimethylhydrazine, and tetramethylhydrazine respectively. The previously reported  $\Delta H_f^\circ$  for tetramethylhydrazine was shown to be erroneous.

## 2.18 Bond Dissociation Energies of MMH

Like hydrazine itself, MMH readily decomposes under the influence of heat or energetic radiation. The most labile part of the molecule is the N—N bond. Various methods have been applied to measure the N—N bond energy and N—N bond dissociation energy in MMH and compare it with that of hydrazine or other methylhydrazines (Table 19). A common method is to observe the appearance potentials in a mass spectrometer. The knowledge of the bond dissociation energy of MMH and other hydrazine-

**Table 19:** Bond dissociation energies in methylhydrazines in comparison to hydrazine.

| Bond                                                                  | Dissociation energy |          |        | References |
|-----------------------------------------------------------------------|---------------------|----------|--------|------------|
|                                                                       | kJ/mol              | kcal/mol | eV     |            |

| H <sub>2</sub> N—NH <sub>2</sub>                                      | 251                 | 60       | —      | [198, 199] |

based fuels is helpful when examining thermal stability, photolysis, autodecomposition temperature, and accidental explosions of these compounds.

A combined Density Functional Theory (DFT) theoretical study gave the following predicted bond dissociation enthalpies (BDEs) and vapor phase enthalpies of formation ( $H_f$ ) for hydrazine, MMH, UDMH, and SDMH: BDE in kJ/mol: N<sub>2</sub>H<sub>4</sub>, 278 ± 4; MMH, 272 ± 4; UDMH, 259 ± 12; SDMH, 272 ± 12.  $H_f$  in kJ/mol: N<sub>2</sub>H<sub>4</sub>, 95 ± 6; MMH, 94 ± 4; UDMH, 80 ± 4; SDMH, 91 ± 4 [205]. The BDEs for the cleavage of the N—N bond decreases in the order N<sub>2</sub>H<sub>4</sub> > MMH > UDMH > SDMH. For hydrazine, for example, the bond dissociation enthalpy is the enthalpy  $\Delta H$  of the following reaction forming two radicals H<sub>2</sub>N• in their equilibrium configuration:

The bond enthalpy (BE) for the N—N bond in hydrazine itself amounts to BE(N—N, H<sub>2</sub>N—NH<sub>2</sub>) = 159 ± 4 kJ/mol. For MMH, the bond dissociation equation is:

## 2.19 Computational Chemistry Calculations of MMH Molecular Structure

Force Field (FF) computations were performed for hydrazine and organic hydrazine derivatives, including MMH, UDMH, ethylhydrazine, and 2-hydroxyethylhydrazine [189]. The FF computations successfully reproduced a range of equilibrium properties, including vapor-liquid coexistence densities, vapor pressures, enthalpies of vaporization, and critical properties. Using this as a basis, a FF method was also developed for the protonated forms of these species, i.e., hydrazinium cations. Properties of 1:1 energetic salts formed by pairing these cations with the nitrate anion were computed and compared with a limited amount of experimental data.

## 2.20 Electrical Properties of MMH

### 2.20.1 Electrical Conductivity of MMH

Methylhydrazine as a non-aqueous solvent is not as good a conductor as its parent compound, hydrazine. The electrical conductance of propellant-grade MMH is lower by about a factor of 7 than that of  $\text{N}_2\text{H}_4$ . Propellant-grade MMH had a specific conductance of  $0.13 \times 10^{-4}$  mho/cm at 298 K [206]. Treatment with BaO removed some of the contaminants (most likely methylcarbamic acid) and lowered the specific conductance to  $0.03 \times 10^{-4}$  mho/cm. The specific resistance of MMH between 283 and 323 K can be expressed by the equation:

$$\Omega = 8.2 \times \exp[1135/(T - 273)]$$

where  $\Omega$  is the specific resistance in Ohm cm and  $T$  is the temperature in kelvin [207, 208]. The difference between the conductivities of two commercial samples of MMH was substantial, amounting to 25%.

### 2.20.2 Dielectric Constant and Dipole Moment of MMH

Measurements of the dielectric constant of MMH/water mixtures are not only useful for studying the internal structure of such liquids but can also serve in the rapid analysis of MMH/water mixtures. The dielectric constants of MMH (DC = 19) and water (DC = 80.1 at 293 K) are sufficiently apart that an instrument could be calibrated to give direct readouts. The dielectric constant of MMH is 19.2 at 288.7 K and 17.3 at 305.3 K [80]. Other sources gave a dielectric constant of MMH of 19.0 at 298 K [79].

Earlier attempts to analyze small quantities (<10%) of water in hydrazine or MMH had failed because the dielectric constants of the two liquids were too close to each other for the oscillometer instrument used [209]. In UDMH, the water content between 0.01 and 1 mass-% could be determined with an average error of 2.2%. The methylhydrazines are less polar liquids and the dielectric constants are correspondingly lower (e.g., 19 for MMH).

Liquid propellant level gauging in a rotating spacecraft can be achieved by capacitance measurements of the liquid-filled space between two concentric tubes serving as the electrodes of a capacitor. Dielectric properties (permittivity and specific conductivity) of MON-1 and MMH were measured as a function of temperature because these numbers were needed for calibrating the sensors [207, 208]. The permittivity of MMH between 283 and 323 K can be expressed by the following equation:

$$\varepsilon = 23.1 - 0.11 \times (T - 273)$$

where  $\varepsilon$  is the permittivity (a dimensionless number) and  $T$  is the temperature in kelvin.

The CNDO/2 calculations of dipole moments and charge distributions for hydrazine and nine substituted hydrazines gave satisfactory agreement between calculated and experimental values [210]. Calculated dipole moments (in Debye units) were  $\text{N}_2\text{H}_4$  2.37, MMH 2.49, UDMH 2.93, 1,2-dimethylhydrazine 0.06, *cis*-trimethylhydrazine 3.37, *trans*-trimethylhydrazine 0.18, and propionyl hydrazine 2.6. N–N bond enthalpies can also be calculated using this method.

The dipole moment calculated for the “outer” skew rotamer of MMH, 1.91 D, was closer to the measured moment of 1.68 D than a calculated moment of 1.13 D for the “inner” configuration [163, 211].

### 2.20.3 Electric Properties of MMH/ $\text{H}_2\text{O}$ Mixtures

The dielectric relaxation times and static permittivity of binary mixtures of MMH/water and UDMH/water were determined in supercooled conditions down to 150 K to study the association between MMH and water in the liquid and solid state [212]. For each system, these properties can be modeled using chemical associations of the type  $(\text{H}_2\text{O}) \bullet (\text{RR}'\text{NNH}_2)$ , and also self-associations for pure hydrazines. Permittivity  $\varepsilon'$  and dielectric loss factor  $\varepsilon''$  define the complex permittivity  $\varepsilon = \varepsilon' - i\varepsilon''$ . Capacitance and dielectric loss factor measurements were taken for eight frequencies – 2 MHz, 1 MHz, 400, 200, 100, 40, 20, and 10 kHz – on an automatic microprocessor-based LRC meter. As spontaneous crystallization occurred on cooling within a certain range of compositions, the relaxation phenomenon could be studied only for the following molar fractions  $\chi$  in alkylhydrazine:  $0.2 < \chi < 0.9$  for the MMH/water system. The maximum relaxation time was located near the molar fraction  $\chi = 0.30 - 0.35$  for the MMH–water mixtures. This behavior is closely related to that observed for viscosity [107].

## 2.21 Base Strength and Protonization of MMH

Alkylation of hydrazine reduces its base strength. Alkylhydrazines are less likely to form double-protonated salts. Table 20 is a comparison of the base strengths and heats of neutralization of methylhydrazines in comparison with hydrazine.

**Table 20:** Base strength, heat of neutralization, and heat of ionization of hydrazines.

| Gross formula  | Abbreviated compound structure | $pK_a$ at 298 K | Heat of neutralization |          | Heat of ionization |          | References |
|----------------|--------------------------------|-----------------|------------------------|----------|--------------------|----------|------------|

## 2.22 Nuclear Magnetic Resonance Spectra of Alkylhydrazines

Nuclear magnetic resonance spectra of alkylhydrazines, either from the nitrogen or carbon nuclei or the hydrogen nuclei (protons) are useful for determining the structure of alkylhydrazine molecules. NMR spectra of anhydrous substituted hydrazines were reported in [218].

## 3 Physical Properties of MMH Mixtures

### 3.1 Physical Properties of MMH/Hydrazine Mixtures

The most frequently used hydrazine/MMH mixture is the 14 mass-% hydrazine/86% MMH mixture (“M-86,” “MHF-3”) with a freezing point of 219 K (−65 °F). Another mixture of practical interest is Ae-76, a blend of 76% MMH and 24% hydrazine formulated by Aerojet to contain the same amount of carbon as Aerozine-50 and at one time intended as a replacement for Ae-50. It freezes at ~237 K (−33 °F). A third blend of interest

is M-20, containing 20% MMH in hydrazine, which freezes at  $\sim 269\text{K}$  ( $25^\circ\text{F}$ ), and it was proposed as a replacement for hydrazine in bipropellant rocket engines to reach lower storage temperatures.

### 3.2 Physical Properties of MMH/Water Mixtures

#### 3.2.1 Freezing Points of MMH/Water Mixtures

The freezing points of MMH/water mixtures are summarized in Table 21. Mixtures with 56% MMH became viscous between 253 and 233 K ( $-20$  and  $-40^\circ\text{C}$ ) and formed glassy solids at about 193 to 187 K ( $-80$  to  $-86^\circ\text{C}$ ). No crystallization could be induced.

**Table 21:** Freezing points of methylhydrazine/water solutions.

| Methylhydrazine<br>Mass-% | Water<br>Mass-% | Liquidus<br>K | Solidus<br>K | Liquidus<br>$^\circ\text{C}$ | Solidus<br>$^\circ\text{C}$ |
|---------------------------|-----------------|---------------|--------------|------------------------------|-----------------------------|
| 29.8                      | 70.2            | 254.1         | 189.1        | $-19.0$                      | $-84.0$                     |
| 34.9                      | 65.1            | 248.1         | 187.1        | $-25.0$                      | $-86.0$                     |
| 40.2                      | 59.8            | 240.6         | 189.1        | $-32.5$                      | $-84.0$                     |
| 44.9                      | 55.1            | a             | a            | a                            | a                           |
| 49.6                      | 50.4            | a             | a            | a                            | a                           |
| 55.9                      | 44.1            | a             | a            | a                            | a                           |
| 60.2                      | 39.8            | a             | a            | a                            | a                           |
| 64.9                      | 35.1            | a             | a            | a                            | a                           |
| 70.0                      | 30.0            | a             | a            | a                            | a                           |
| 75.2                      | 24.8            | a             | a            | a                            | a                           |
| 80.6                      | 19.4            | a             | a            | a                            | a                           |
| 85.4                      | 14.6            | a             | a            | a                            | a                           |
| 88.2                      | 11.8            | a             | a            | a                            | a                           |
| 94.3                      | 5.7             | 213.1         | 195.1        | $-60.0$                      | $-78.0$                     |

<sup>a</sup> These solutions became viscous between 253 and 233 K ( $-20$  and  $-40^\circ\text{C}$ ) and formed glassy solids at about 193 to 187 K ( $-80$  to  $-86^\circ\text{C}$ ). No crystallization could be induced.

Data source: [60]

Freezing point data shown in Figure 22 indicate that MMH and water form a hydrate similar to what hydrazine does [99]. Similar conclusions can be drawn based on viscosity data. The composition of the hydrate is 28%  $\text{H}_2\text{O}$  and 72% MMH. It contains water and MMH in a 1:1 molar ratio and forms a congruent compound. A liquid with this composition has a sharp freezing point ( $213\text{K} = -78^\circ\text{F}$ ) and when cooled to this temperature and below freezes to a solid with the same composition. In Figure 22, the symbol  $\Lambda$  designates the liquid solution,  $\alpha$  is water ice,  $\beta$  is frozen MMH hydrate, and  $\gamma$  is frozen MMH.

**Figure 22:** Solid–liquid phase diagram for the methylhydrazine/H<sub>2</sub>O system. (Reproduced and modified from [22] as adapted from [99].)

Crystallization kinetics of MMH monohydrate were followed under adiabatic conditions and the measurements indicated that two solid phases, a metastable form and a stable form, exist between 186 and 223 K [219]. This method allows one to determine the temperature dependence of the growth process of the metastable solid in only one experiment. The spontaneous evolution of the system temperature with time during the crystallization process was modeled assuming a temperature dependence of the growth rate and using the Avrami–Kolmogorov assumption. The results suggested that the number of nuclei is constant during the growth process and that the crystallites grow with a constant shape in the undercooled liquid. Figure 23 shows that MMH and water form a monohydrate that exists in a metastable (dashed line) and a stable form (solid line) at temperatures between 186 and 223 K.
